An impressionistic painting in dark, moody tones. It depicts a person, possibly a woman, wearing a vibrant red garment. The figure is positioned on the right side of the frame, looking down. The background is a blend of dark purples, blues, and browns, with visible brushstrokes and a textured, painterly quality. The overall mood is somber and artistic.

**European
Association
of Urology**

Introduction

We are honoured and privileged to introduce you to the 2015 update of the EAU Guidelines. The Guidelines are a priority for the EAU, they are a priority for every practicing urologist across Europe and beyond, and importantly, they are a priority for the continued improvement of patient care and outcomes. This means that the EAU Guidelines are by default an important priority for healthcare policy-makers and funders. The EAU Guidelines Office oversees the production of 20 International Guidelines across 20 Guideline Panels. Our Guideline panels have some of the most respected, talented and dedicated urologists from across the breadth of Europe and beyond that work on a voluntary basis for the Guidelines Office.

For this 2015 print, observant readers will notice a decrease in size of all individual guidelines topics based on structured templates (oncology- and non-oncology) developed by the EAU Guidelines Office Methods sub-Committee. All texts have been subjected to a robust double blind peer review process prior to publication.

In mapping out the future of the EAU Guidelines over the next 5 years, our readership will witness increasing standardisation of the structure of the guidelines, high quality systematic reviews underpinning key recommendations, and increasing standardisation in phrasing of actionable recommendations. In order to meet this requirement of high quality systematic reviews underpinning recommendations, the Guidelines Office has embarked on systematically introducing Cochrane review methodology across all 20 Guideline panels. This process is ongoing and the benefits and impact of this transition will be seen in this and future updates of the EAU Guidelines. The past year has seen a considerable uptake of new systematic review projects, the results of which will become more apparent to the readers in each subsequent update.

Strengthening the evidence base that underpin EAU Guidelines recommendations and improving the transparency from evidence to recommendations is a critical area the EAU Guidelines Office must continue to be vigilant about. More meaningful involvement of patients in the development of the EAU guidelines is another area that the EAU is investing in. After all, we produce guideline recommendations for urologists to use in their daily practice but the recommendations are not applied to urologists, they are applied to patients, and so we are committed to ensuring that the clinical questions the recommendations are based on, and the outcomes of interest that are considered, take important patient views into account. Difficult as such a transition may be, that is our responsibility, if we are to maintain our position at the cutting edge of quality international guideline production.

Important as it is to produce comprehensive high quality clinical practice guidelines, more effective dissemination and assessment of their value in day-to-day clinical practice is crucial and the EAU Guidelines Office is well positioned now to embark on this programme of work. Doing so, could provide further insight into what may well be more optimum ways to present our findings in the future, thereby making EAU guideline recommendations more relevant and actionable, also enhancing their influence on patient care.

The EAU Guidelines Office is embracing New Media tools (Facebook / Twitter) as a means to enhance not only the dissemination of the EAU guidelines but also to promote discussion and feedback from our users. We are counting on your active engagement in helping us with this endeavor, which is led by a dedicated Guidelines Office Dissemination sub-Committee.

The yearly publication of the EAU Guidelines would not be possible without the trust and support of each and every user of the Guidelines globally, our EAU membership, our valued Guideline panels, the young Guideline Associates, the EAU Executive Committee & Management team, our EAU National Societies, and importantly, the Guidelines Office staff (especially Karin Plass, Esther Robijn and Eva Lowther). So, on behalf of the EAU Guidelines Office Board, thank you for your support and inspiration.

We hope you enjoy using the 2015 update of the EAU Guidelines!

The EAU Guidelines Office has set up dedicated sub-Committees responsible for critical aspects of guidelines development. The Methods sub-Committee, supported by methodologists, is charged with the development of methodological standards and quality control. The Dissemination sub-Committee oversees the development of dissemination and implementation strategies.

Methodology section

In this 2015 EAU Guidelines compilation, all standard information on levels of evidence (LE) and grading of recommendations (GR) has been taken out of the individual guidelines topics for the sake of brevity.

Recommendations and statements issued in the EAU guidelines are based on the following system, modified from the Oxford Centre for Evidence-based Medicine [1].

Table 1.1: Level of evidence [1]*

Level	Type of evidence
1a	Evidence obtained from meta-analysis of randomised trials.
1b	Evidence obtained from at least one randomised trial.
2a	Evidence obtained from one well-designed controlled study without randomization.
2b	Evidence obtained from at least one other type of well-designed quasi-experimental study.
3	Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports.
4	Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities.

Table 1.2: Grade of recommendation [1]*

Grade	Nature of recommendations
A	Based on clinical studies of good quality and consistency addressing the specific recommendations and including at least one randomised trial.
B	Based on well-conducted clinical studies, but without randomised clinical trials.
C	Made despite the absence of directly applicable clinical studies of good quality.

** Modified from [1].*

The aim of assigning a LE and grading recommendations is to provide transparency between the underlying evidence and the recommendation given.

It should be noted that when recommendations are graded, the link between the level of evidence and grade of recommendation is not directly linear. Availability of randomized controlled trials may not necessarily translate into a grade A recommendation where there are methodological limitations or disparity in published results. Alternatively, absence of high level evidence does not necessarily preclude a grade A recommendation, if there is overwhelming clinical experience and consensus. In addition, there may be exceptional situations where corroborating studies cannot be performed, perhaps for ethical or other reasons and in this case unequivocal recommendations are considered helpful for the reader. The quality of the underlying scientific evidence - although a very important factor - has to be balanced against benefits and burdens, values and preferences and costs when a grade is assigned.

The EAU Guidelines Office do not perform cost assessments, nor can they address local/national preferences in a systematic fashion. But whenever this data is available, the panel will include the information.

The Assistance and support of the European National Urological Associations has been invaluable for the European Association of Urology guidelines project over the past years. Whilst in many European countries the EAU guidelines are being used in clinical practice, or form the basis of national urological guidelines, the EAU Guidelines Office have recently started to formalise endorsement of their guidelines. Formal replies have been sent in by the following National Urological Associations:

National Societies Endorsements

- The Algerian Association of Urology
- The Argentinian Society of Urology
- The Armenian Association of Urology
- The Austrian Urological Society
- The Belarusian Association of Urology
- La Sociedad Chilena de Urología
- La Sociedad Colombiana de Urología
- The Cyprus Urological Association
- The Czech Urological Society
- The Dutch Association of Urology
- The German Urological Association
- The Hellenic Urological Association
- The Hong Kong Urological Association
- The Hungarian Urological Association
- The Indonesian Urological Association
- The Italian Association of Urology
- The Kosova Urological Association
- The Latvian Association of Urology
- The Macedonian Association of Urology
- The Malaysian Urological Association
- The Polish Urological Association
- The Portuguese Urological Association
- The Russian Society of Urology
- The Slovenian Urological Association
- The Swedish Urology Association
- The Spanish Association of Urology
- The Taiwan Urological Association
- The Turkish Association of Urology
- The Ukrainian Association of Urology

Acknowledgement of reviewers - 2015 edition of the EAU Guidelines

Reviewers were identified based on their expert knowledge within the urological field and bordering specialties. The EAU Guidelines Office Board is most grateful for their time and diligence in providing complete and extensive reviews of the individual EAU Guidelines. Whenever feasible, feedback from lay reviewers and patient advocacy groups has been sought.

Listing of reviewers is alphabetical.

1. INTRODUCTION

1.1 Aims and scope

This overview represents the updated European Association of Urology (EAU) guidelines for Non-muscle-invasive Bladder Cancer (NMIBC) Ta, T1 and CIS. The information presented is limited to urothelial carcinoma, unless specified otherwise. The aim is to provide practical guidance on the clinical management of NMIBC with a focus on clinical presentation and recommendations.

Separate EAU guidelines documents are available addressing upper tract urothelial carcinomas (UTUCs) [1], muscle-invasive and metastatic bladder cancer (MIBC) [2], and primary urethral carcinomas [3].

1.2 Panel composition

The EAU Guidelines Panel on NMIBC consists of an international multidisciplinary group of clinicians, including a pathologist and a statistician. Members of this panel have been selected based on their expertise and to represent the professionals treating patients suspected of harbouring bladder cancer.

All experts involved in the production of this document have submitted potential conflict of interest statements.

1.3 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices, presenting the main findings of the NMIBC Guidelines. These are abridged versions which may require consultation together with the full text versions. Several scientific publications are available, as are a number of translations of all versions of the EAU NMIBC Guidelines. All documents can be accessed through the EAU website Uroweb: <http://www.uroweb.org/guidelines/online-guidelines/>.

1.4 Publication history and summary of changes

1.4.1 Publication history

The first EAU Guidelines on Bladder Cancer were published in 2000. This 2015 MIBC guidelines document presents a limited update of the 2014 full text document.

1.4.2 Summary of changes

Key changes for this 2015 print:

- The literature for the complete document has been assessed and updated, whenever relevant.
- A new section on resection techniques has been added, also expanding on the significance of biopsy for bladder cancer pathology.
- The sections on the role of imaging for initial diagnosis and follow-up have been updated.
- The sections on stratification of patients into risk groups and high-risk disease have been enlarged.
- A new section on Bacillus Calmette-Guérin (BCG) is included and the section on intravesical BCG and immunotherapy schedule has been expanded in this 2015 version of the NMIBC Guidelines.

Recommendations have been rephrased and added to throughout the current document, not resulting in a change in the grade of recommendation (GR). New recommendations have been included in sections:

5.14 Guidelines for TURB and/or biopsies, tumour classification and pathology report

	GR
Avoid cauterization as much as possible during TURB to avoid tissue deterioration.	C
In patients with positive cytology, but negative cystoscopy, exclude a UTUC, CIS in the bladder (random biopsies or PDD targeted biopsies) and tumour in prostatic urethra (prostatic urethra biopsy).	C
If indicated, perform a second TURB within 2-6 weeks after initial resection. It should include resection of the primary tumour site.	C
Classification and pathological report	
Do not use the term "Superficial BC".	A
In difficult cases, consider an additional review by an experienced genitourinary pathologist.	B

CIS = carcinoma in situ; PDD = photodynamic diagnosis; TURB = transurethral resection of the bladder.

6.3.1 Recommendations for stratification of NMIBC

	GR
In patients treated with BCG, use CUETO risk tables for individual prediction of the risk of tumour recurrence and progression.	B

7.5 Recommendations for adjuvant therapy in Ta, T1 tumours and for therapy of CIS

	GR
In patients with intermediate-risk tumours, one immediate instillation of chemotherapy should be followed by 1-year full-dose BCG treatment, or by further instillations of chemotherapy for a maximum of 1 year. The final choice should reflect the individual patient's risk of recurrence and progression as well as the efficacy and side effects of each treatment modality.	A
In patients with high-risk tumours, full-dose intravesical BCG for 1-3 years is indicated. The additional beneficial effect of the second and third years of maintenance should be weighed against its added costs and inconvenience.	A
Intravesical chemotherapy	
Give clear instructions to the nursing staff to control the free flow of the bladder catheter at the end of the immediate instillation.	C

8.1 Guidelines for follow-up in patients after TURB of NMIBC

	GR
Consider R-biopsies or biopsies with PDD after intravesical treatment (at 3 or 6 months) in patients with CIS.	C

2. METHODS

2.1 Data Identification

For the current update, all articles published in 2014 and 2015 on NMIBC were considered. A systematic literature search for each section of the NMIBC Guidelines was performed by the Panel members. For identification of original and review articles, Medline, Web of Science, and Embase databases were used. These literature searches focused on identification of all level 1 scientific papers (randomized controlled trials [RCTs], systematic reviews [SRs], and meta-analyses of RCTs).

In this 2015 EAU Guidelines compilation, all standard information on levels of evidence (LE) and grading of recommendations (GR) has been taken out of the individual guidelines topics for the sake of brevity. This information is included in the introductory section of this print.

2.2 Review

This document was subjected to double-blind peer review prior to publication.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Bladder cancer (BC) is the 11th most commonly diagnosed cancer in the world [4]. The worldwide age-standardised incidence rate (per 100,000 person-years) is 8.9 for men and 2.2 for women (2008 data) [4]. In the European Union (EU), the age-standardised incidence rate is 27 for men and six for women [4]. In Europe, the highest age-standardised incidence rate has been reported in Spain (41.5 in men and 4.8 in women) and the lowest in Finland (18.1 in men and 4.3 in women) [4].

Worldwide, BC is the 14th leading cause of cancer deaths, age-standardised mortality rate (per 100,000 person-years) was 3.3 for men versus 0.9 for women in 2008 [4]. In the EU, the age-standardised mortality rate was 8 for men and 3 for women, respectively [4].

BC incidence and mortality rates vary across the countries due to differences in risk factors, detection and diagnostic practices, and availability of treatments. The variations are however partly caused by the different methodology and quality of data collection [5, 6].

The incidence and mortality of BC has decreased in some registries, possibly reflecting the decreased impact of causative agents [6, 7].

Approximately 75% of patients with BC present with a disease confined to the mucosa (stage Ta, CIS) or submucosa (stage T1). They have a high prevalence due to long-term survival in many cases and lower risk of cancer specific mortality compared to T2-4 tumours [5, 8].

3.2 Aetiology

Tobacco smoking is the most important risk factor for BC, accounting for approximately 50% of cases [5, 9-11] (LE: 3). Tobacco smoke contains aromatic amines and polycyclic aromatic hydrocarbons, which are renally excreted.

Occupational exposure to aromatic amines, polycyclic aromatic hydrocarbons and chlorinated hydrocarbons is the second most important risk factor for BC, accounting for about 10% of all cases. This type of occupational exposure occurs mainly in industrial plants processing paint, dye, metal and petroleum products [5, 12-14]. In developed industrial settings, these risks have been reduced by work safety guidelines so that chemical workers no longer have a higher incidence of BC compared to the general population [15].

Genetic predisposition has an influence on the incidence of BC, especially via its impact on susceptibility to other risk factors [5, 16].

Although the significance of the amount of fluid intake is uncertain, the chlorination of drinking water and subsequent levels of trihalomethanes are potentially carcinogenic, while exposure to arsenic in drinking water increases risk [5, 8, 17] (LE: 3). The association between personal hair dye use and risk remains uncertain; an increased risk has been suggested in users of permanent hair dyes with an NAT2 slow acetylation phenotype [18, 19].

Exposure to ionizing radiation is connected with increased risk; weak association was also suggested for cyclophosphamide and pioglitazone [5, 8] (LE: 3). Schistosomiasis, a chronic endemic cystitis, based on recurrent infection with a parasitic trematode, is also a cause of BC [5] (LE: 3).

3.3 Pathology

The information presented in text is limited to urothelial carcinoma, unless specified otherwise.

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Definition of non-muscle-invasive bladder cancer

Papillary tumours confined to the mucosa and invading the lamina propria are classified as stage Ta and T1, respectively, according to the Tumour, Node, Metastasis (TNM) classification system. Flat, high-grade tumours that are confined to the mucosa are classified as CIS (Tis). These tumours can be treated by transurethral resection of the bladder (TURB) and/or intravesical instillations and are therefore grouped under the heading of NMIBC for therapeutic purposes. However, molecular biology techniques and clinical experience have demonstrated the highly malignant potential of CIS and T1 lesions. The terms “NMIBC” and older one “superficial BC” are therefore suboptimal descriptions.

4.2 Tumour, Node, Metastasis Classification (TNM)

The 2002 TNM classification approved by the Union International Contre le Cancer (UICC) was updated in 2009 (7th version), but it had no changes for bladder tumours (Table 4.1) [20].

Table 4.1: 2009 TNM classification of urinary bladder cancer

T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
Tis	Carcinoma <i>in situ</i> : 'flat tumour'
T1	Tumour invades subepithelial connective tissue Tumour invades muscle
T2	T2a Tumour invades superficial muscle (inner half) T2b Tumour invades deep muscle (outer half)
T3	Tumour invades perivesical tissue T3a Microscopically T3b Macroscopically (extravesical mass)
T4	Tumour invades any of the following: prostate, uterus, vagina, pelvic wall, abdominal wall T4a Tumour invades prostate, uterus or vagina T4b Tumour invades pelvic wall or abdominal wall
N - Lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N2	Metastasis in multiple lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N3	Metastasis in common iliac lymph node(s)
M - Distant metastasis	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

4.3 Histological grading of non-muscle-invasive bladder urothelial carcinomas

In 2004, the World Health Organization (WHO) and the International Society of Urological Pathology (ISUP) published a new histological classification of urothelial carcinomas which provides a different patient stratification between individual categories compared to the older 1973 WHO classification [21, 22] (Tables 4.2, 4.3, Fig 4.1). A website (www.pathology.jhu.edu/bladder) that illustrates examples of the various grades has been developed to further improve accuracy in using the system.

Table 4.2: WHO grading in 1973 and in 2004 [21, 22]

1973 WHO grading <i>Urothelial papilloma</i> Grade 1: well differentiated Grade 2: moderately differentiated Grade 3: poorly differentiated
2004 WHO grading system [papillary lesions] <i>Urothelial papilloma (completely benign lesion)</i> Papillary urothelial neoplasm of low malignant potential (PUNLMP) Low-grade (LG) papillary urothelial carcinoma High-grade (HG) papillary urothelial carcinoma

The prognostic value of both WHO 1973 and 2004 grading systems has been confirmed. Attempts to demonstrate better prognostic value of one of them, however, have yielded controversial results [23-28] (LE: 2a). Moreover the WHO 2004 system has not been fully incorporated into prognostic models yet. Most clinical trials published to date on Ta, T1 bladder tumours have been performed using the 1973 WHO classification, and the following guidelines are therefore based on this version.

Figure 4.1: Stratification of tumours according to grade in the WHO 1973 and 2004 classifications [23]*

**1973 WHO Grade 1 carcinomas have been reassigned to papillary urothelial neoplasm of low malignant potential (PUNLMP) and low-grade (LG) carcinomas in 2004 WHO classification, and Grade 2 carcinomas to LG and high-grade (HG) carcinomas. All 1973 WHO Grade 3 carcinomas have been reassigned to HG carcinomas (Reproduced with permission from Elsevier).*

PUNLMP = papillary urothelial neoplasm of low malignant potential; WHO = World Health Organization.

4.4 CIS and its classification

Carcinoma *in situ* (CIS) is a flat, high-grade, non-invasive urothelial carcinoma. It can be missed at cystoscopy or be considered as an inflammatory lesion if it is not biopsied. CIS is often multifocal and can occur in the bladder, but also in the upper urinary tract, prostatic ducts, and prostatic urethra [29].

Classification of CIS into clinical type [30]:

- Primary: isolated CIS with no previous or concurrent papillary tumours and no previous CIS;
- Secondary: CIS detected during follow-up of patients with a previous tumour that was not CIS;
- Concurrent: CIS in the presence of any other urothelial tumour in the bladder.

Table 4.3: WHO 2004 grading system

WHO 2004 grading system (flat lesions):
• Hyperplasia (flat lesion without atypia or papillary aspects)
• Reactive atypia (flat lesion with atypia)
• Atypia of unknown significance
• Urothelial dysplasia
• Urothelial CIS is always high-grade

4.5 Inter- and intra-observer variability in staging and grading

There is significant variability among pathologists for diagnosis of CIS, for which agreement is achieved in only 70-78% of cases [31, 32] (LE: 2a). There is also interobserver variability in the classification of stage T1 versus Ta tumours and tumour grading in both 1997 and 2004 classifications. The general conformity in staging and grading is between 50% and 60% [27, 31-36] (LE: 2a). The published comparisons have not clearly confirmed that the WHO 2004 classification has better reproducibility than the 1973 classification [24, 27].

4.6 Further promising pathology parameters

Some novel parameters based on pathological investigation of resected tissue have been considered for subclassification and prognostic purposes.

In T1 tumours, the depth and extent of invasion into the lamina propria (T1 substaging) can be evaluated. The prognostic value of this evaluation has been demonstrated by some retrospective cohort studies [37-40] (LE: 3); nevertheless, it is not recommended in the WHO classification.

According to a meta-analysis of retrospective trials, the presence of lymphovascular invasion (LVI) in TURB specimens was connected with increased risk of pathological upstaging [41] (LE: 3). Lymphovascular invasion has been reported as an unfavourable prognostic factor in T1 tumours [42] (LE: 3).

Some variants of urothelial carcinoma (micropapillary, plasmocytoid, nested, sarcomatoid, squamous and adeno variants of urothelial carcinoma etc.), have a poor prognosis [43-47] (LE: 3).

Molecular markers, particularly FGFR3 mutation status, are promising but need further evaluation [25, 40, 48-50].

4.7 Recommendations

The recommendations for BC classification can be found in section 5.14.

5. DIAGNOSIS

5.1 Patient history

A comprehensive patient history is mandatory.

5.2 Signs and symptoms

Haematuria is the most common finding in NMIBC. Ta, T1 tumours do not cause bladder pain and rarely present with lower urinary tract symptoms. CIS might be suspected in patients who do complain of these symptoms, particularly if they are refractory to symptomatic treatment.

5.3 Physical examination

Physical examination does not reveal NMIBC.

5.4 Imaging

5.4.1 Computed tomography urography and intravenous urography

Computed tomography (CT) urography is used to detect papillary tumours in the urinary tract, which can be seen as filling defects or indicated by hydronephrosis.

Intravenous urography (IVU) can be an alternative if CT is not available [51] (LE: 3), but particularly in muscle-invasive tumours of the bladder and in UTUCs, CT urography gives more information than IVU does (including status of lymph nodes and neighbouring organs).

The necessity to perform a baseline CT urography or IVU once a bladder tumour has been detected is questioned because of the low incidence of significant findings obtained [52-54] (LE: 2a). The incidence of UTUCs is low (1.8%), but increases to 7.5% in tumours located in the trigone [53] (LE: 2b). The risk of UTUC during follow-up increases in patients with multiple- and high-risk tumours [55] (LE: 3).

5.4.2 Ultrasound (US)

Transabdominal US permits characterization of renal masses, detection of hydronephrosis, and visualization of intraluminal masses in the bladder. It is as accurate as IVU for diagnosis of UTUC [52] (LE: 3). Ultrasound is therefore a useful tool for detection of obstruction in patients with haematuria. However, it cannot exclude the presence of UTUC and cannot replace CT urography.

The diagnosis of CIS cannot be made with imaging methods (CT urography, IVU or US) (LE: 4).

5.5 Urinary cytology

The examination of voided urine or bladder-washing specimens for exfoliated cancer cells has high sensitivity in G3 tumours, but low sensitivity in G1 tumours. The sensitivity in CIS detection is 28-100% [56] (LE: 2b). Cytology is useful, particularly as an adjunct to cystoscopy, when a G3 malignancy or CIS is present. Positive voided urinary cytology can indicate an urothelial tumour anywhere in the urinary tract; negative cytology, however, does not exclude the presence of a tumour.

Cytological interpretation is user-dependent [57]. Evaluation can be hampered by low cellular yield, urinary tract infections, stones, or intravesical instillations, but in experienced hands specificity exceeds 90% [58] (LE: 2b). Urine collection should respect recommendations (see Section 5.9). One cytospin slide from the sample is usually sufficient [59]. In patients with suspect cytology it is reasonable to repeat the investigation [60] (LE: 3).

5.6 Urinary molecular marker tests

Driven by the low sensitivity of urine cytology, numerous urinary tests were developed [58, 61-68]. None of these markers have been accepted for diagnosis or follow-up in routine urology or in guidelines. Some urine tests that have been evaluated in several laboratories/centres and with sufficient numbers of patients are listed in Table 5.1.

The following conclusions can be drawn regarding the existing tests.

- Sensitivity is usually higher and at the cost of lower specificity compared to urine cytology [58, 62-72] (LE: 3).
- Benign conditions and BCG influence many urinary marker tests [58, 61-68] (LE: 3).
- Sensitivity and specificity of a urinary marker test depend on the clinical context of the patient

- (screening, primary detection, follow-up [high risk, low-/intermediate-risk]) [62-65] (LE: 3).
- Patient selection explains the wide range in performance of the markers listed in Table 5.1.
- Unlike other urine tests, false-positive results of UroVysion and microsatellite analysis can be attributed to occult disease and thus identify patients likely to experience early recurrence [73-77] (LE: 3).

Table 5.1: Summary of main urinary markers

Markers (or test specifications)	Overall sensitivity (%)	Overall specificity (%)	Sensitivity for high-grade tumours (%)	Point-of-care test	LE
UroVysion (FISH)	30-86	63-95	66-70	No	2b
Microsatellite analysis	58-92	73-100	90-92	No	1b
Immunocyt/uCyt +	52-100	63-79	62-92	No	2a
Nuclear matrix Protein 22	47-100	55-98	75-92	Yes	2a
BTA stat	29-83	56-86	62-91	Yes	3
BTA TRAK	53-91	28-83	74-77	No	3
Cytokeratins	12-88	73-95	33-100	No	3

BTA = bladder tumour antigen; LE = level of evidence.

5.7 Potential application of urinary cytology and markers

The following objectives of urinary cytology or molecular tests must be considered.

5.7.1 Screening of the population at risk of BC

The application of haematuria dipstick, NMP22 or UroVysion in BC screening in high-risk populations has been reported [78, 79]. The low incidence of BC in the general population and the short lead-time impair feasibility and cost-effectiveness [65, 77-79]. Routine application of screening is not recommended.

5.7.2 Exploration of patients after haematuria or other symptoms suggestive of BC (primary detection)

It is generally accepted that none of the tests can replace cystoscopy. However, urinary cytology or markers can be used as an adjunct to cystoscopy to detect invisible tumours, particularly CIS. In this setting, sensitivity for high-grade tumours and specificity are particularly important. Urinary cytology is highly specific, but urinary markers lack this high specificity and are not recommended for primary detection.

5.7.3 Surveillance of NMIBC

Research has been carried out into the usefulness of urinary cytology versus markers in the follow-up of NMIBC [65, 67, 80, 81].

5.7.3.1 Follow-up of high-risk NMIBC

High-risk tumours should be detected early in follow-up, and the percentage of tumours missed should be as low as possible. Therefore, the best surveillance strategy for these patients will continue to include frequent cystoscopy and cytology.

5.7.3.2 Follow-up of low-/intermediate-risk NMIBC

To reduce the number of cystoscopy procedures, urinary markers should be able to detect recurrence before the tumours are large and numerous. The limitation of urinary cytology is its low sensitivity for low-grade recurrences. Several urinary markers are better, but still do not detect half of the low-grade tumours identified by cystoscopy [62, 65] (LE: 3).

According to current knowledge, no urinary marker can replace cystoscopy during follow-up or help to lower cystoscopic frequency in a routine fashion. One prospective randomized study confirmed that knowledge of positive test results (microsatellite analysis) can improve the quality of follow-up cystoscopy [82] (LE: 1b). It supports the adjunctive role of a non-invasive urine test performed before follow-up cystoscopy [82].

5.8 Cystoscopy

The diagnosis of papillary BC ultimately depends on cystoscopic examination of the bladder and histological evaluation of the resected tissue. CIS is diagnosed by a combination of cystoscopy, urine cytology, and

histological evaluation of multiple bladder biopsies [83].

Cystoscopy is initially performed in the office. A flexible instrument with topical intra-urethral anaesthetic lubricant instillation results in better compliance compared to a rigid instrument, especially in men [84].

Figure 5.1: Bladder diagram

5.9 Guidelines for the primary assessment of NMIBC

	GR
Patient history should be taken.	A
Renal and bladder US may be used during the initial work-up in patients with haematuria.	C
At the time of the initial diagnosis of NMIBC, CT urography (or IVU) should be performed only in selected cases (e.g., tumours located in the trigone, multiple- or high-risk tumours).	B
Cystoscopy is recommended in all patients with symptoms suggestive of BC. It cannot be replaced by cytology or by any other non-invasive test.	A
Cystoscopy should describe all macroscopic features of the tumour (site, size, number and appearance) and mucosal abnormalities. A bladder diagram is recommended (Figure 5.1).	C
Voided urine cytology is advocated to predict high-grade tumour before TURB.	C
Cytology should be performed on fresh urine with adequate fixation. Morning urine is not suitable because of the frequent presence of cytolysis.	C

BC = bladder cancer; CT = computed tomography; GR = grade of recommendation; IVU = intravenous urography; US = ultrasound; NMIBC = non-muscle invasive bladder cancer; TURB = transurethral resection of the bladder.

5.10 Transurethral resection of Ta, T1 bladder tumours

5.10.1 Strategy of the procedure

The goal of TURB in Ta,T1 BC is to make the correct diagnosis and completely remove all visible lesions. It is a crucial procedure in the diagnosis and treatment of BC. TURB should be performed systematically in individual steps (see Section 5.14). The strategy of resection depends on the size of the lesion (see Section 5.14). Separate resection of larger tumours provides good information about the vertical and horizontal extent of the tumour and helps to improve resection completeness [85, 86] (LE: 3).

Complete and correct TURB is essential to achieve a good prognosis [87]. It has been confirmed that the absence of detrusor muscle in the specimen is associated with a significantly higher risk of residual disease, early recurrence and tumour understaging [86, 88] (LE: 2b). It has been shown that surgical experience can improve TURB results, which supports the role of teaching programmes [89].

5.10.2 **Office-based fulguration**

In patients with a history of small, Ta LG/G1 tumours, fulguration of small papillary recurrences on an outpatient basis can reduce the therapeutic burden and can be a treatment option [90] (LE: 3).

5.10.3 **New resection techniques**

Compared to monopolar resection, the bipolar electrocautery system has been introduced to reduce the risk of complications (e.g., bladder perforation due to obturator nerve stimulation) and produce better specimens for the pathologist [91] (LE: 3). As yet, the results are controversial [92-94].

5.10.4 **Bladder and prostatic urethral biopsies**

Carcinoma *in situ* can present as a velvet-like, reddish area indistinguishable from inflammation, or it may not be visible at all. For this reason, the strategy of biopsies from abnormal urothelium and biopsies from normal-looking mucosa (random/mapping biopsies) was recommended (see Section 5.14). The indication of random biopsies reflects the fact, that the likelihood of detecting CIS, especially in low-risk tumours, is extremely low (< 2%) [95] (LE: 2a). The risk increases in patients with high-risk tumours and with positive cytology [96].

If equipment is available, photodynamic diagnosis (PDD) is a useful tool to target the biopsy (see Section 5.11.1).

Involvement of the prostatic urethra and ducts in men with NMIBC has been reported. Palou et al. [97] showed that in 128 men with T1G3 BC, the incidence of CIS in the prostatic urethra was 11.7% (LE: 2b). The risk of prostatic urethra- or duct involvement is higher if the tumour is located on the trigone or bladder neck, in the presence of bladder CIS and multiple tumours [98] (LE: 3). Based on this observation a biopsy from the prostatic urethra is necessary in some cases. A recommendation is included in Section 5.14 [97, 99].

5.11 **New methods of tumour visualization**

As a standard procedure, cystoscopy and TURB are performed using white light. However, the use of white light can lead to missing lesions that are present but not visible, which is why new technologies are being developed.

5.11.1 **Photodynamic diagnosis (fluorescence cystoscopy)**

Photodynamic diagnosis (PDD) is performed using violet light after intravesical instillation of 5-aminolaevulinic acid (ALA) or hexaminolaevulinic acid (HAL). It has been confirmed that fluorescence-guided biopsy and resection are more sensitive than conventional procedures for detection of malignant tumours, particularly for CIS [100, 101] (LE: 2a). In a systematic review and meta-analysis, PDD had higher sensitivity than white-light endoscopy in the pooled estimates for analyses at both the patient-level (92% versus 71%) and biopsy-level (93% versus 65%) [101].

PDD had lower specificity than white-light endoscopy (63% vs. 81%) [101]. False-positivity can be induced by inflammation or recent TURB and during the first 3 months after BCG instillation [102, 103] (LE: 3). Prospective randomized studies evaluating the impact of ALA fluorescence-guided (FC) TURB on disease recurrence rate provided controversial results [101, 104, 105].

The beneficial effect of HAL FC on recurrence rate in patients with TURB was confirmed by a multicentre, prospective, randomized trial and by raw-data based meta-analysis of controlled trials. A meta-analysis reported in HAL arms an increase in detection of tumour lesions across all risk groups and an absolute reduction of < 10% in recurrence rates within 12 months [106] (LE: 1a). The beneficial effect of HAL FC on recurrence rate in patients with TURB and early intravesical instillation of chemotherapy was not confirmed by a prospective randomized trial [107]. The value of FC for improvement of outcome in relation to progression rate, survival and clinical management remains to be demonstrated.

5.11.2 **Narrow-band imaging**

In narrow-band imaging (NBI), the contrast between normal urothelium and hyper-vascular cancer tissue is enhanced. Initial studies have demonstrated improved cancer detection by NBI-guided biopsies and resection [108, 109] (LE: 3). The suggested reduction of recurrence rate if NBI is used during TURB has not been fully confirmed yet [110].

5.12 **Second resection**

The significant risk of residual tumour after initial TURB of Ta, T1 lesions has been demonstrated [87] (LE: 2a).

Persistent disease after resection of T1 tumours has been observed in 33-55% of patients, and after resection of TaG3 tumour in 41.4% [111-115].

Moreover, the tumour is often understaged by initial resection. The likelihood that muscle-invasive disease is detected by second resection of initially T1 tumour ranges from 4-25%, and it increases to 45% if there was no muscle in the initial resection [86]. This risk has increased up to 50% in some radical cystectomy (RC) series, although these studies only enrolled selected patients [116-118] (LE: 2a). Treatment of a Ta, T1 high-grade tumour and a T2 tumour is completely different; correct staging is therefore important.

It has been demonstrated that a second TURB can increase recurrence-free survival [111, 112] (LE: 2a), improve outcomes after BCG treatment [119] (LE: 3) and provide prognostic information [116, 120] (LE: 3)

Based on these arguments, a second TURB is recommended in selected cases (see Section 5.14).

5.13 Pathology report

Pathology investigation of the specimen obtained by TURB and biopsies is an essential step in the diagnosis and treatment decision-making process for BC. Close co-operation between urologists and pathologists is recommended.

A high quality of resected and submitted tissue is essential for correct pathological assessment. The presence of sufficient muscle is necessary for the correct assignment of T category. To achieve all required information, the specimen collection, handling and evaluation should respect the recommendations provided below (section 5.14) [121].

5.14 Guidelines for TURB and/or biopsies, tumour classification and pathology report

	GR
Perform TURB systematically in individual steps: <ul style="list-style-type: none"> • bimanual palpation under anaesthesia; • insertion of the resectoscope, under visual control with inspection of the whole urethra; • inspection of the whole urothelial lining of the bladder; • biopsy from prostatic urethra (if indicated); • cold-cup bladder biopsies (if indicated); • resection of the tumour; • surgical report formulation; • precise description of the specimen for pathology evaluation. 	C
Performance of individual steps:	
Perform resection in one piece for small papillary tumours (< 1 cm), including a part from the underlying bladder wall.	B
Perform resection in fractions including the exophytic part of the tumour, the underlying bladder wall with the detrusor muscle, and the edges of the resection area for tumours > 1 cm in diameter.	B
Avoid cauterization as much as possible during TURB to avoid tissue deterioration.	C
Take biopsies from abnormal-looking urothelium.	
Biopsies from normal-looking mucosa (trigone, bladder dome, and right, left, anterior and posterior bladder walls) are recommended when cytology is positive or when high-risk exophytic tumour is expected (non-papillary appearance).	C
Take biopsy of the prostatic urethra in cases of bladder neck tumour, when bladder CIS is present or suspected, when there is positive cytology without evidence of tumour in the bladder, or when abnormalities of the prostatic urethra are visible. If biopsy is not performed during the initial procedure, it should be completed at the time of the second resection.	C
Take the biopsy from abnormal areas in the prostatic urethra and from the precollicular area (between the 5 and 7 o'clock position) using a resection loop. In primary non-muscle-invasive tumours when stromal invasion is not suspected, the cold-cup biopsy with forceps can be used.	C
If equipment is available, use fluorescence-guided (PDD) biopsy instead of random biopsies when bladder CIS or high-grade tumour is suspected (e.g., positive cytology, recurrent tumour with previous history of a high-grade lesion).	B
Refer the specimens from different biopsies and resection fractions to the pathologist in separate containers and label them separately.	C
TURB protocol must describe tumour appearance, all steps of the procedure, as well as the extent and completeness of resection.	C
In patients with positive cytology, but negative cystoscopy, exclude a UTUC, CIS in the bladder (random biopsies or PDD targeted biopsies) and tumour in the prostatic urethra (prostatic urethra biopsy).	C

Perform a second TURB in the following situations: <ul style="list-style-type: none"> • after incomplete initial TURB; • if there is no muscle in the specimen after initial resection, with the exception of TaG1 tumours and primary CIS; • in all T1 tumours; • in all G3 tumours, except primary CIS. 	A
If indicated, perform a second TURB within 2-6 weeks after initial resection. It should include resection of the primary tumour site.	C
Classification and pathological report	
For classification of the depth of tumour invasion (staging) use the 2009 TNM system.	A
For histological classification, use both the 1973 and 2004 WHO grading.	A
Do not use the term "Superficial BC".	A
Whenever using the terminology NMIBC, in individual cases, mention the tumour stage and grade.	A
The pathological report should specify tumour location, tumour grade, depth of tumour invasion, presence of CIS, and whether the detrusor muscle is present in the specimen.	A
The pathological report should specify the presence of LVI or unusual (variant) histology.	C
In difficult cases, consider an additional review by an experienced genitourinary pathologist.	B

BC = bladder cancer; CIS = carcinoma in situ; CT = computed tomography; LVI = lymphovascular invasion; PDD = photodynamic diagnosis; TNM = Tumour, Node, Metastasis; TURB = transurethral resection of the bladder; WHO = World Health Organisation.

6. PREDICTING DISEASE RECURRENCE AND PROGRESSION

6.1 Ta, T1 tumours

In order to predict separately the short- and long-term risks of disease recurrence and progression in individual patients, the European Organization for Research and Treatment of Cancer (EORTC) Genito-Urinary Cancer Group (GUCG) has developed a scoring system and risk tables [122]. The basis for these tables are individual patient data for 2,596 patients diagnosed with Ta, T1 tumours, who were randomized into seven EORTC-GUCG trials. Patients with CIS alone were not included. Seventy-eight percent of patients received intravesical treatment, mostly chemotherapy. However, they did not undergo a second TURB or receive maintenance BCG.

The scoring system is based on the six most significant clinical and pathological factors which are shown in Table 6.1.

It also illustrates the weights applied to various factors for calculating the total scores for recurrence and progression. Table 6.2 shows the total scores stratified, as in the original article [122], into four categories that reflect various probabilities of recurrence and progression at 1 and 5 years (LE: 2a).

Table 6.1: Weighting used to calculate disease recurrence and progression scores

Factor	Recurrence	Progression
Number of tumours		
Single	0	0
2-7	3	3
≥ 8	6	3
Tumour diameter		
< 3 cm	0	0
≥ 3	3	3
Prior recurrence rate		
Primary	0	0
≤ 1 recurrence/year	2	2
> 1 recurrence/year	4	2
Category		
Ta	0	0
T1	1	4
Concurrent CIS		
No	0	0
Yes	1	6
Grade		
G1	0	0
G2	1	0
G3	2	5
Total Score	0-17	0-23

Table 6.2: Probability of recurrence and disease progression according to total score

Recurrence score	Probability of recurrence at 1 year		Probability of recurrence at 5 years	
	%	(95% CI)	%	(95% CI)
0	15	(10-19)	31	(24-37)
1-4	24	(21-26)	46	(42-49)
5-9	38	(35-41)	62	(58-65)
10-17	61	(55-67)	78	(73-84)

Progression score	Probability of progression at 1 year		Probability of progression at 5 years	
	%	(95% CI)	%	(95% CI)
0	0.2	(0-0.7)	0.8	(0-1.7)
2-6	1	(0.4-1.6)	6	(5-8)
7-13	5	(4-7)	17	(14-20)
14-23	17	(10-24)	45	(35-55)

NB: Electronic calculators for Tables 6.1 and 6.2, which have been updated for the iPhone, iPad and Android phones and tablets, are available at <http://www.eortc.be/tools/bladdercalculator/>.

A scoring model for BCG-treated patients that predicts the short- and long-term risks of recurrence and progression has been published by the Club Urológico Español de Tratamiento Oncológico (CUETO) (Spanish Urological Oncology Group). It is based on an analysis of 1,062 patients from four CUETO trials that compared different intravesical BCG treatments. Patients received 12 instillations over 5-6 months. No immediate postoperative instillation or second TURB was performed in these patients. The scoring system is based on the evaluation of seven prognostic factors:

- sex;
- age;
- prior recurrence status;
- number of tumours;
- T category;
- associated CIS;
- tumour grade.

Using these tables, the calculated risk of recurrence is lower than that obtained by the EORTC tables. For progression, probability is lower only in high-risk patients [123] (LE: 2a). The lower risks in the CUETO tables may be attributed to using BCG, which is a more effective instillation therapy. The CUETO risk calculator is available at: <http://www.aeu.es/Cueto.html>.

The prognostic value of the EORTC scoring system has been confirmed by data from the CUETO patients treated with BCG and by long-term follow-up in an independent patient population [124, 125] (LE: 2a).

Further prognostic factors have been described in selected patient populations:

- In T1G3 tumours important prognostic factors were female sex and CIS in the prostatic urethra in patients treated with an induction course of BCG, and age, tumour size and concurrent CIS in BCG treated patients (62% with induction course only) [97, 126] (LE: 2b).
- Attention must be given to patients with T1G3 tumours in bladder (pseudo) diverticulum because of an absence of muscle layer in the diverticular wall [127] (LE: 3).
- In patients with high-risk disease, the tumour stage at the time of the 2nd TURB is an unfavourable prognostic factor [116, 120] (LE: 3)
- In patients with T1G2 tumours treated with TURB, recurrence at 3 months was the most important predictor of progression [128] (LE: 2b).
- The prognostic value of pathological factors has been discussed elsewhere (see Section 4.6). More research is needed to determine the role of molecular markers in improving the predictive accuracy of currently existing risk tables [124, 129].

6.2 Carcinoma *in situ*

Without any treatment, approximately 54% of patients with CIS progress to muscle-invasive disease [130] (LE: 3). Unfortunately, there are no reliable prognostic factors that can be used to predict the course of the disease. Publications are based on retrospective analyses of small series of patients and conclusions are not homogeneous. Some studies have reported a worse prognosis in concurrent CIS and T1 tumours compared to primary CIS [131, 132], in extended CIS [133], and in CIS in the prostatic urethra [97] (LE: 3).

The response to intravesical treatment with BCG or chemotherapy is an important prognostic factor for subsequent progression and death caused by BC [123-125, 128]. Approximately 10-20% of complete responders eventually progress to muscle-invasive disease, compared with 66% of non-responders [134, 135] (LE: 2a).

6.3 Patients' stratification into risk groups

To facilitate treatment recommendations it is important to categorise patients into risk groups. Based on available prognostic factors and in particular data from the EORTC risk tables, the Guidelines Panel recommends stratification of patients into three risk groups. Table 6.3 provides a definition of these risk groups, which takes into account the EORTC risk tables' probabilities of recurrence and especially progression.

Table 6.3: Risk group stratification

Risk group stratification	Characteristics
Low-risk tumours	Primary, solitary, Ta, G1* (PUNLMP, LG), < 3 cm, no CIS
Intermediate-risk tumours	All tumours not defined in the two adjacent categories (between the category of low- and high-risk).
High-risk tumours	Any of the following: <ul style="list-style-type: none"> • T1 tumour • G3** (HG) tumour • CIS • Multiple and recurrent and large (> 3 cm) Ta G1G2 tumours (all conditions must be presented in this point)*

Substratification of high-risk tumours for clinical purposes can be seen in Table 7.2.

**low grade is a mixture of G1 and G2*

*** high grade is a mixture of some G2 and all G3 (see Figure 4.1)*

CIS = carcinoma in situ; HG = high-grade; LG = low-grade.

6.3.1 Recommendations for stratification of NMIBC

	GR
Stratify patients into three risk groups according to Table 6.2.	B
Apply the EORTC risk tables and calculator for individual prediction of the risk of tumour recurrence and progression in different intervals after TURB.	B
In patients treated with BCG, use the CUETO risk tables for individual prediction of the risk of tumour recurrence and progression.	B

BCG = *Bacillus Calmette-Guérin*; CUETO = *Club Urológico Español de Tratamiento Oncológico*; GR = grade of recommendation; EORTC = *European Organization for Research and Treatment of Cancer*; TURB = *transurethral resection of the bladder*.

7. DISEASE MANAGEMENT

7.1 Counselling of smoking cessation

It has been confirmed that smoking increases the risk of tumour recurrence and progression [136, 137] (LE: 3).

While it is still controversial whether smoking cessation in bladder cancer will favourably influence the outcome of BC treatment, patients should be counselled to stop smoking due to the general risks connected with tobacco smoking [138-140, 141] (LE: 3).

7.2 Adjuvant treatment

7.2.1 Intravesical chemotherapy

Although TURB by itself can eradicate a Ta, T1 tumour completely, these tumours commonly recur and can progress to MIBC. The high variability in the 3-month recurrence rate indicates that the TURB was incomplete or provokes recurrences in a high percentage of patients [87]. It is therefore necessary to consider adjuvant therapy in all patients.

7.2.1.1 A single, immediate, post-operative intravesical instillation of chemotherapy

Immediate single instillation (SI) has been shown to act by the destruction of circulating tumour cells resulting from TURB, and by an ablative effect (chemoresection) on residual tumour cells at the resection site and on small overlooked tumours [142-145] (LE: 3).

Three large meta-analyses comprising 1,476 to 3,103 patients have consistently shown that SI after TURB significantly reduced the recurrence rate by 11.7% to 13.0% compared to TURB alone [146-148] (LE: 1a). Although none of the three meta-analyses adequately answered the question concerning which patients benefitted the most, some underpowered data from two subgroup analyses [149, 150] suggest that SI is most effective in tumour types with the lowest tendency towards recurrence, i.e., in single primary or small tumours. Mitomycin C (MMC), epirubicin, and doxorubicin have all shown a beneficial effect; no efficacy comparisons have been made [146-148] (LE: 1a).

There is evidence from one subgroup- and one combined analysis that SI might have an impact on recurrence, even when further adjuvant instillations are given [151-153] (LE: 2a). In contrast, a sufficient number of delayed repeat chemotherapy instillations can also reduce recurrence stemming from tumour implantation [151-154]. Clearly, more studies comparing immediate and delayed-start regimens are needed.

The prevention of tumour cell implantation should be initiated within the first hours after cell seeding. Within a few hours, the cells are implanted firmly and are covered by extracellular matrix [142, 155-157] (LE: 3). In all SI studies, the instillation was administered within 24 hours. To maximize the efficacy of SI, one should devise flexible practices that allow the instillation to be given as early as possible, which is in the recovery room or even in the operating theatre.

As severe complications have been reported in patients with drug extravasation [158, 159], safety measures should be maintained (see Section 7.5).

7.2.1.2 Additional adjuvant intravesical chemotherapy instillations

The need for further adjuvant intravesical therapy depends on prognosis. In low-risk patients (Tables 6.1, 6.2 and 6.3), a SI reduces the risk of recurrence and is considered to be the standard and sufficient treatment [146] (LE: 1a). For other patients, however, a SI remains an incomplete treatment because of the considerable likelihood of recurrence and/or progression (Tables 6.1, 6.2 and 6.3). It was shown that further chemotherapy instillations can improve RFS in intermediate-risk tumours [154].

A large meta-analysis of 3,703 patients from 11 randomized trials showed a highly significant

44% reduction in the odds of recurrence at one year in favour of chemotherapy over TURB alone [160]. This corresponds to an absolute difference of 13-14% in the number of patients with recurrence. Contrary to chemotherapy, two meta-analyses have demonstrated that BCG therapy may reduce the risk of tumour progression [161, 162] (LE: 1a) (see Section 8.2.1). Moreover, BCG maintenance therapy appears to be significantly better in preventing recurrences than chemotherapy [163-165] (see Section 7.2.2) (LE: 1a). However, BCG causes significantly more side effects than does chemotherapy [165] (LE: 1a).

The length and frequency of chemotherapy instillations is still controversial. A systematic review of RCTs, comparing different schedules of intravesical chemotherapy instillations, concluded that the ideal duration and intensity of the schedule remains undefined because of conflicting data [153]. The available evidence does not support treatment longer than one year (LE: 3).

7.2.1.3 Options for improving efficacy of intravesical chemotherapy

Some promising data have been presented on enhancing the efficacy of MMC using microwave-induced hyperthermia or electromotive drug administration (EMDA) in patients with high-risk tumours. The current evidence, however, is limited [166, 167] and both treatment modalities are considered to be experimental (LE: 2b).

One RCT using MMC has demonstrated that adapting urinary pH, decreasing urinary excretion, and buffering the intravesical solution reduced the recurrence rate [168] (LE: 1b). Another trial reported that a 1-hour instillation of MMC was more effective than 30 minutes instillation, but no efficacy comparisons are available for 1- and 2-hour instillations [169] (LE: 3). Another RCT using epirubicin has documented that concentration is more important than treatment duration [170] (LE: 1b). In view of these data, instructions are provided (see Section 7.5)

7.2.2 Intravesical bacillus Calmette-Guérin (BCG) immunotherapy

7.2.2.1 Efficacy of BCG

Five meta-analyses have confirmed that BCG after TURB is superior to TURB alone or TURB + chemotherapy for preventing the recurrence of NMIBC [163, 171-174] (LE: 1a). Three recent RCTs of intermediate- and high-risk tumours have compared BCG with epirubicin + interferon [175], MMC [176], or epirubicin alone [164] and have confirmed the superiority of BCG for prevention of tumour recurrence (LE: 1a). The effect is long-lasting [164, 176] and was also observed in a separate analysis of patients with intermediate-risk tumours [164].

One meta-analysis [163] has evaluated the individual data from 2,820 patients enrolled in nine RCTs that have compared MMC versus BCG. In the trials with BCG maintenance, there was a 32% reduction in the risk of recurrence for BCG compared to MMC, but a 28% increase in the risk of recurrence for patients treated with BCG in the trials without BCG maintenance.

Two meta-analyses have demonstrated that BCG therapy prevents, or at least delays, the risk of tumour progression [161, 162] (LE: 1a). A meta-analysis carried out by the EORTC-GUCG has evaluated data from 4,863 patients enrolled in 24 RCTs. Five different BCG strains were used, and in 20 of the trials, some form of BCG maintenance was used. Based on a median follow-up of 2.5 years, in 260 out of 2,658 patients (9.8%) treated with BCG, tumours progressed compared to 304 out of 2,205 (13.8%) in the control groups (TURB alone, TURB + intravesical chemotherapy, or TURB + other immunotherapy). This shows a reduction of 27% in the odds of progression with BCG maintenance treatment. The size of the reduction was similar in patients with Ta, T1 papillary tumours and in those with CIS [162]. A recent RCT with long-term observation has demonstrated significantly fewer distant metastases and better overall- and disease-specific survival in patients treated with BCG compared to epirubicin [164] (LE: 1b). On the contrary, a meta-analysis of individual patient data was not able to confirm any statistically significant difference between MMC and BCG for progression, survival and cause of death [163].

The conflicting results in the outcomes of these studies can be explained by different patient characteristics, duration of follow-up, methodology and statistical power. However, most studies showed a reduction in the risk of progression in high- and intermediate-risk tumours if BCG was applied including a maintenance schedule.

Two other meta-analyses have suggested a possible bias in favour of BCG arising from the inclusion of patients previously treated with intravesical chemotherapy [177]. In the most recent meta-analysis, however, BCG maintenance was more effective than MMC both in patients previously treated and not previously treated with chemotherapy [163] (LE: 1a).

It was demonstrated that BCG was less effective in patients > 70 years of age, but it was still more effective than epirubicin [178] (LE: 1a).

According to a published meta-analysis of 4 RCTs, the addition of chemotherapy to maintenance BCG does not improve the efficacy [179]. One smaller RCT demonstrated promising results of the addition of electromotive administered MMC to BCG, however, this requires further confirmation [167].

7.2.2.2 BCG strain

The EORTC meta-analysis suggested no large differences in efficacy between various BCG strains [162]. Recently published smaller studies without maintenance demonstrated some differences between strains. This clearly needs further evaluation in prospective trials [180, 181] (LE: 2a).

7.2.2.3 BCG toxicity

BCG intravesical treatment is associated with more side effects compared to intravesical chemotherapy [162] (LE: 1a). However, serious side effects are encountered in < 5% of patients and can be treated effectively in almost all cases [182] (LE: 1b). It has been shown that a maintenance schedule is not associated with an increased risk of side effects compared to an induction course [182]. Side effects requiring treatment stoppage were seen more often in the first year of therapy [183].

Major complications can appear after systemic absorption of the drug. Thus, contraindications of BCG intravesical instillation should be respected (see Section 7.5).

The presence of leukocyturia, non-visible haematuria or asymptomatic bacteriuria is not a contraindication for BCG application, and antibiotic prophylaxis is not necessary in these cases [184, 185] (LE: 3).

BCG should be used with caution (relative contraindication) in immunocompromised patients (immunosuppression, human immunodeficiency virus [HIV] infection) [186], although some small studies have shown similar efficacy and no increase in complications compared to non-immunocompromised patients [187, 188] (LE: 3).

The management of side effects after BCG should reflect their type and grade according the recommendations provided by the International Bladder Cancer Group (IBCG) and by a Spanish group [189, 190] (Table 7.1).

Table 7.1: Management options for side effects associated with intravesical BCG [190-193]

Management options for local side effects (modified from the IBCG group)	
Symptoms of cystitis	Phenazopyridine, propantheline bromide, or NSAIDs.
	If symptoms improve within a few days: continue instillations.
	If symptoms persist or worsen: a. Postpone the instillation; b. Perform a urine culture; c. Start empirical antibiotic treatment.
	If symptoms persist even with antibiotic treatment: d. With positive culture: antibiotic treatment according to sensitivity e. With negative culture: quinolones and potentially analgesic anti-inflammatory instillations once daily for 5 days (repeat cycle if necessary) [191].
	If symptoms persist: anti-tuberculosis drugs + corticosteroids.
	If no response to treatment and/or contracted bladder: radical cystectomy.
Haematuria	Perform urine culture to exclude haemorrhagic cystitis, if other symptoms present.
	If haematuria persists, perform cystoscopy to evaluate presence of bladder tumour.
Symptomatic granulomatous prostatitis	Symptoms rarely present: perform urine culture.
	Quinolones.
	If quinolones are not effective: isoniazid (300 mg/day) and rifampicin (600 mg/day) for 3 months.
	Cessation of intravesical therapy.
Epididymo-orchitis [192]	Perform urine culture and administer quinolones.
	Cessation of intravesical therapy.
	Orchidectomy if abscess or no response to treatment.

Management options for systemic side effects	
General malaise, fever	Generally resolve within 48 hours, with or without antipyretics.
Arthralgia and/or arthritis	Rare complication and considered autoimmune reaction.
	Arthralgia: treatment with NSAIDs.
	Arthritis: NSAIDs.
	If no/partial response, proceed to corticosteroids, high-dose quinolones or anti-tuberculosis drugs [193].
Persistent high-grade fever (> 38.5°C for > 48 h)	Permanent discontinuation of BCG instillations.
	Immediate evaluation: urine culture, blood tests, chest X-ray.
	Prompt treatment with > two antimicrobial agents while diagnostic evaluation is conducted.
	Consultation with an infectious diseases specialist.
BCG sepsis	Prevention: initiate BCG at least 2 weeks post-TURB (if no signs and symptoms of haematuria).
	Cessation of BCG.
	For severe infection:
	<ul style="list-style-type: none"> • High-dose quinolones or isoniazid, rifampicin and ethambutol 1.2 g daily for 6 months. • Early, high-dose corticosteroids as long as symptoms persist. Consider an empirical non-specific antibiotic to cover Gram-negative bacteria and/or Enterococcus.
Allergic reactions	Antihistamines and anti-inflammatory agents.
	Consider high-dose quinolones or isoniazid and rifampicin for persistent symptoms.
	Delay therapy until reactions resolve.

BCG = *bacillus Calmette-Guérin*; IBCG = *International Bladder Cancer Group*; NSAID = *non-steroidal anti-inflammatory drug*; TURBT = *transurethral resection of bladder tumour*.

7.2.2.4 Optimal BCG schedule

Induction BCG instillations are given according to the empirical 6-weekly schedule introduced by Morales in 1976 [194]. For optimal efficacy, BCG must be given in a maintenance schedule [161-163, 174] (LE: 1a). Many different maintenance schedules have been used, ranging from a total of 10 instillations given in 18 weeks to 27 over 3 years [195]. The EORTC meta-analysis was unable to determine which BCG maintenance schedule was the most effective [162]. In their meta-analysis, Böhle et al. concluded that at least one year of maintenance BCG is required to obtain superiority of BCG over MMC for prevention of recurrence or progression [161] (LE: 1a).

The optimal number of induction instillations and optimal frequency and duration of maintenance instillations remain unknown [196]. However, in a RCT of 1,355 patients, the EORTC has shown that when BCG is given at full dose, 3 years' maintenance reduces the recurrence rate compared to one year in high- but not in intermediate-risk patients. There were no differences in progression or overall survival. In the 3-year arm, however, 36.1% of patients did not complete the 3-years schedule [197] (LE: 1b). The benefit of the two additional years of maintenance in the high-risk patients should be weighed against its added costs and inconvenience.

7.2.2.5 Optimal dose of BCG

To reduce BCG toxicity, instillation of a reduced dose was proposed. However, it has been suggested that a full dose of BCG is more effective in multifocal tumours [198, 199] (LE: 1b). The CUETO study compared one-third dose to full-dose BCG and found no overall difference in efficacy. One-third of the standard dose of BCG might be the minimum effective dose for intermediate-risk tumours. A further reduction to one-sixth dose resulted in a decrease in efficacy with no decrease in toxicity [200] (LE: 1b).

The EORTC did not find any difference in toxicity between one-third and full-dose BCG, but one-third dose BCG was associated with a higher recurrence rate, especially when it was given only for one year [183, 197] (LE: 1b). Moreover, the routine application is complicated by potential technical difficulties in preparing the reduced dose reliably.

7.2.2.6 Indications for BCG

Although BCG is a very effective treatment, there is a consensus that not all patients with NMIBC should be treated with BCG due to the risk of toxicity. Ultimately, the choice of treatment depends upon the patient's risk (Table 6.2). The recommendation for individual risk groups is provided in Section 7.5.

7.2.3 **Specific aspects of treatment of CIS**

7.2.3.1 *Treatment strategy*

The detection of concurrent CIS increases the risk of recurrence and progression of Ta,T1 tumours [122, 123], further treatment according to the criteria summarized in Sections 7.2.1, 7.2.2, 7.3 and 7.4 is mandatory.

CIS cannot be cured by an endoscopic procedure alone. Histological diagnosis of CIS must be followed by further treatment, either intravesical BCG instillations or RC (LE: 4). Tumour-specific survival rates after immediate RC for CIS are excellent, but as many as 40-50% of patients might be over-treated [130] (LE: 3).

7.2.3.2 *Cohort studies on intravesical BCG or chemotherapy*

In retrospective evaluations of patients with CIS, a complete response rate of 48% was achieved with intravesical chemotherapy and 72-93% with BCG [130-133, 201] (LE: 2a). Up to 50% of complete responders might eventually show recurrence with a risk of invasion and/or extravesical recurrence [133, 195, 201, 202] (LE: 3).

7.2.3.3 *Prospective randomized trials on intravesical BCG or chemotherapy*

Unfortunately, there have been few randomized trials in patients with CIS alone. A meta-analysis of clinical trials comparing intravesical BCG to intravesical chemotherapy in patients with CIS has shown a significantly increased response rate after BCG and a reduction of 59% in the odds of treatment failure with BCG [203] (LE: 1a).

In an EORTC-GUCG meta-analysis of tumour progression (a subgroup of 403 patients with CIS), BCG reduced the risk of progression by 35% as compared to intravesical chemotherapy or different immunotherapy [162] (LE: 1b). The combination of BCG and MMC is not superior to BCG alone [204]. In summary, compared to chemotherapy, BCG treatment of CIS increases the complete response rate, the overall percentage of patients who remain disease free, and reduces the risk of tumour progression (LE: 1a).

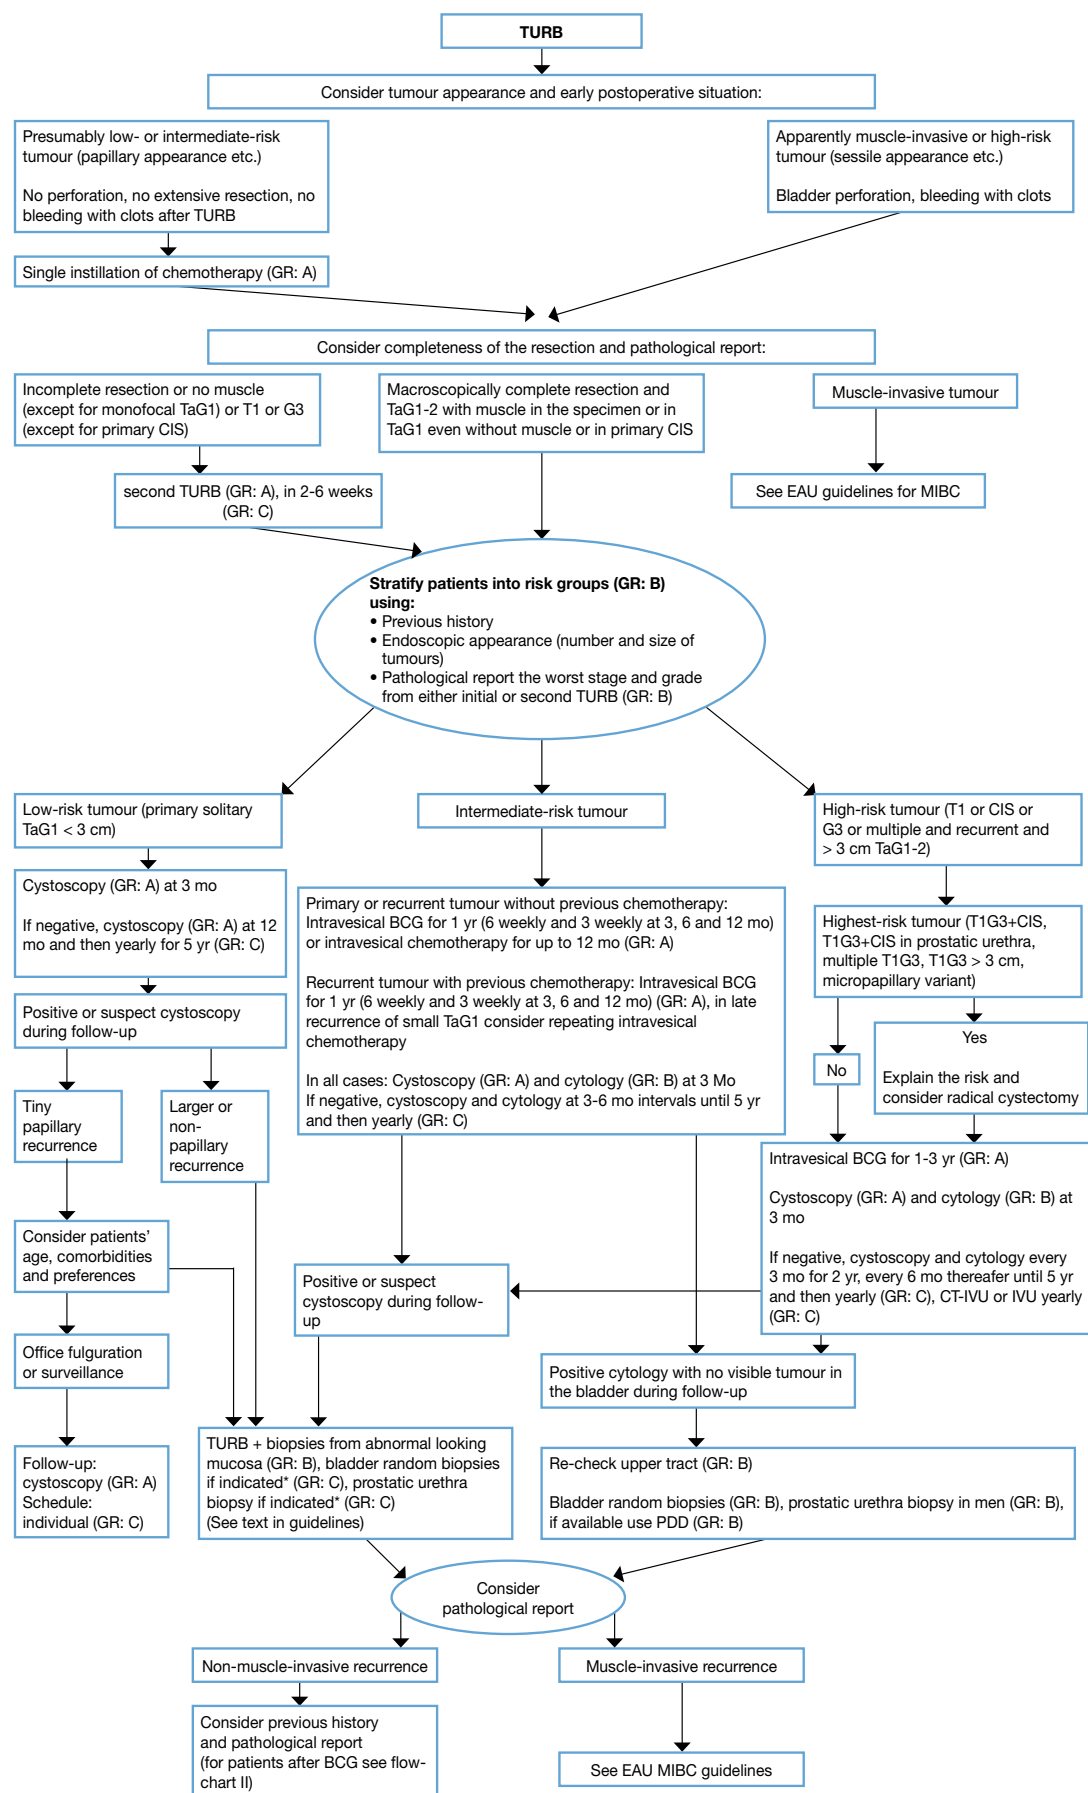

7.2.3.4 *Treatment of extravesical CIS*

Patients with CIS are at high risk of extravesical involvement in the UUT and in the prostatic urethra. Solsona et al. found that 63% of 138 patients with CIS developed extravesical involvement initially or during follow-up [205]. Patients with extravesical involvement had worse survival than those with bladder CIS alone [205] (LE: 3).

In the prostate, CIS might be present only in the epithelial lining of the prostatic urethra or in the prostatic ducts [29]. These situations should be distinguished from tumour invasion into the prostatic stroma (stage T4a in bladder tumours), and for which immediate radical cystoprostatectomy is mandatory. Patients with CIS in the epithelial lining of the prostatic urethra can be treated by intravesical instillation of BCG. TUR of the prostate can improve contact of BCG with the prostatic urethra [84, 206] (LE: 3).

In patients with prostatic duct involvement, there are promising results after BCG instillation, but only from small series, so the data are insufficient to provide clear treatment recommendations and radical surgery should be considered [206, 207] (LE: 3). Treatment of CIS that involves the UUT is discussed in the Guidelines on Urothelial Tumours of the Upper Urinary Tract (UTUCs).

Flowchart 7.1: Treatment strategy in primary or recurrent tumour(s) without previous BCG*

*For details and explanations see the text of the guidelines

BCG = bacillus Calmette-Guérin; GR = grade of recommendation; MIBC = muscle-invasive bladder cancer; PDD = photodynamic diagnosis; TURB = transurethral resection of the bladder.

7.3 Treatment of failure of intravesical therapy

7.3.1 Failure of intravesical chemotherapy

Patients with non-muscle-invasive recurrence of BC after a chemotherapy regimen can benefit from BCG instillations. Prior intravesical chemotherapy has no impact on the effect of BCG instillation [163] (LE: 1a).

7.3.2 Recurrence and failure after intravesical BCG immunotherapy

Table 7.2: Categories of unsuccessful treatment with intravesical BCG

BCG failure
Whenever a MIBC is detected during follow-up.
BCG-refractory tumour: 1. If high-grade, non-muscle-invasive papillary tumour is present at 3 months [208]. Further conservative treatment with BCG is associated with increased risk of progression [134, 209] (LE: 3). 2. If CIS (without concomitant papillary tumour) is present at both 3 and 6 months. In patients with CIS present at 3 months, an additional BCG course can achieve a complete response in > 50% of cases [29] (LE: 3). 3. If high-grade tumour appears during BCG therapy*.
High-grade recurrence after BCG. Recurrence of high-grade/grade 3 (WHO 2004/1973) tumour after completion of BCG maintenance, despite an initial response [210] (LE: 3)*.
BCG intolerance
Severe side effects that prevent further BCG instillation before completing induction [190].

* Patients with low-grade recurrence during or after BCG treatment are not considered to be a BCG failure. BCG = bacillus Calmette-Guérin; CIS = carcinoma in situ; LE = level of evidence.

7.3.3 Treatment of BCG failure and recurrences after BCG

Treatment recommendations are provided in Table 7.4. They reflect categories mentioned in Table 7.2 and tumour characteristics at the time of recurrence.

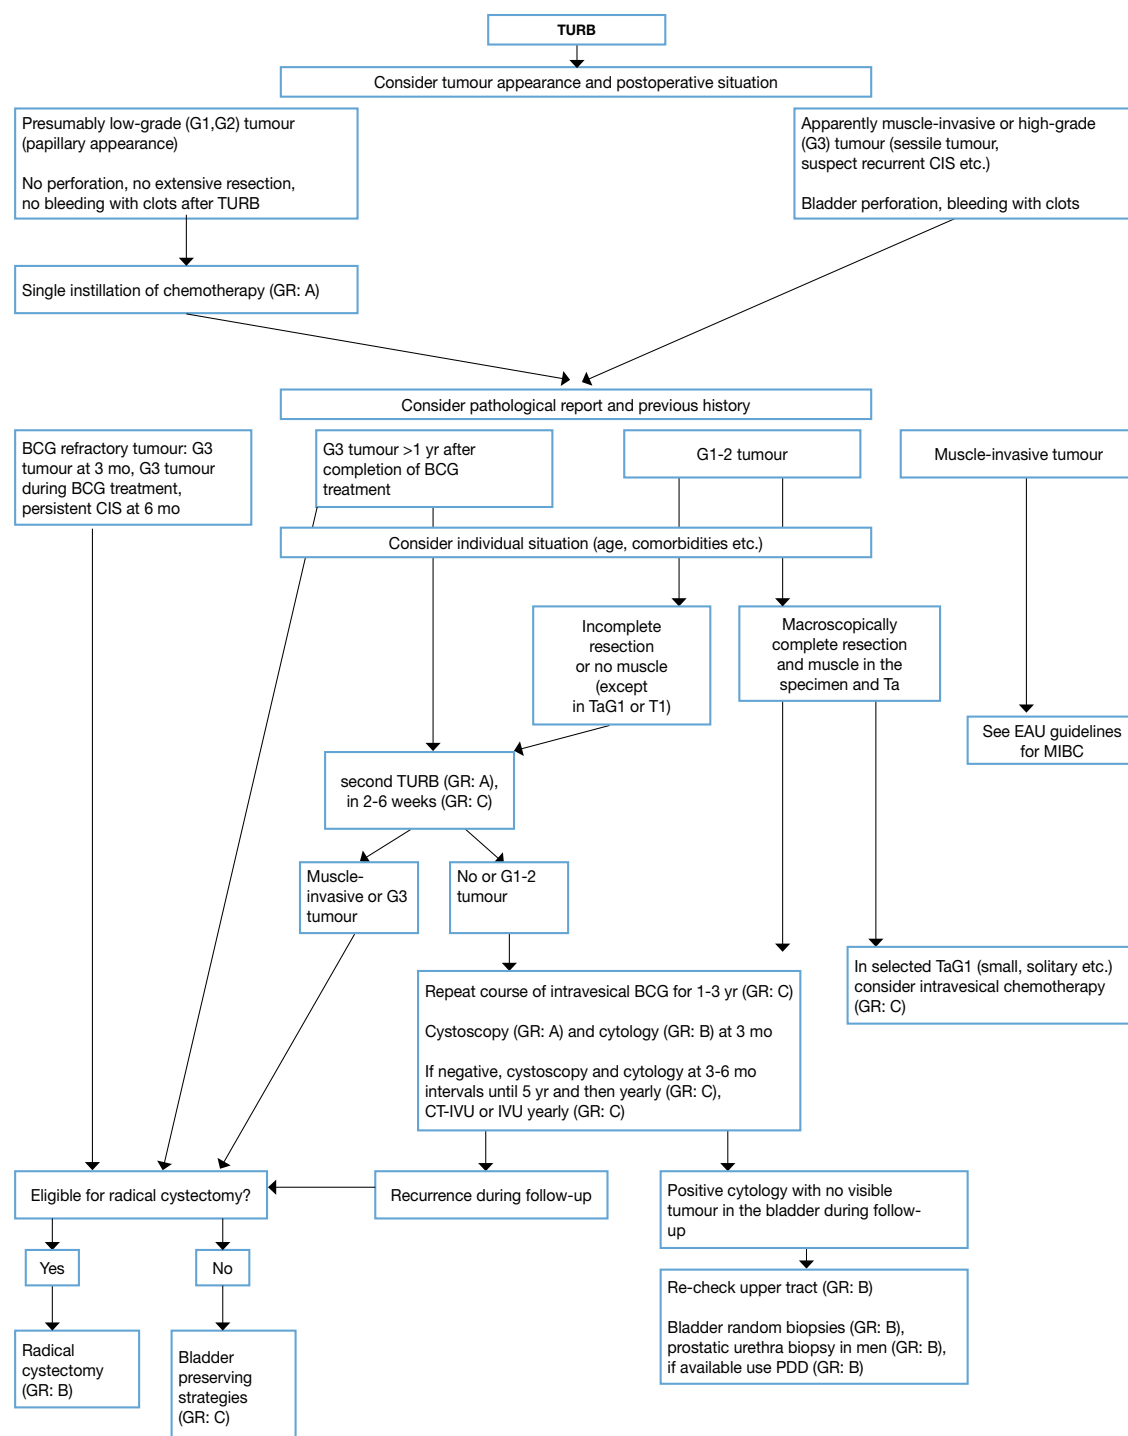

Patients with BCG failure are unlikely to respond to further BCG therapy; RC is therefore the preferred option. Various studies suggest that repeat BCG therapy is appropriate for non-high grade and even for some high-grade recurrent tumours [211, 212] (LE: 3). Additionally, there are now several bladder preservation strategies available that can be categorized as immunotherapy, chemotherapy, device-assisted therapy, and combination therapy [213]. Changing from BCG to these options can yield responses in selected cases with BCG treatment failure [211, 214-221] (LE: 3).

Treatments other than RC must be considered oncologically inferior in patients with BCG failure at the present time [134, 208, 209] (LE: 3).

Little is known about the optimal treatment in patients with high-risk tumours who could not complete BCG instillations because of intolerance.

Non-high grade recurrence after BCG is not considered as BCG failure. Treatment decision should be individual according to the tumour characteristics. It could include chemotherapy or repeat BCG instillations, but the published evidence is very low.

Flowchart 7.2: Treatment strategy in recurrence during or after intravesical BCG*

*For details and explanations, see the text of the guidelines.

BCG = bacillus Calmette-Guérin; GR = grade of recommendation; IVU = intravenous urography; PDD = photodynamic diagnosis; TURB = transurethral resection of the bladder.

7.4 Radical cystectomy for NMIBC

If RC is indicated before progression to muscle-invasive tumour, it can be performed as an immediate (immediately after NMIBC diagnosis) or early (after BCG failure) procedure.

There are several reasons to consider immediate RC for selected patients with NMIBC:

- The staging accuracy for T1 tumours by TURB is low with 27-51% of patients being upstaged to muscle-invasive tumour at RC [99, 117, 222-227] (LE: 3).
- Some patients with NMIBC experience disease progression to muscle-invasive disease (Table 6.2).

The potential benefit of RC must be weighed against the risk, morbidity, and impact on quality of life. It is reasonable to propose immediate RC in those patients with NMIBC who are at highest risk of progression (see Table 7.3) [44, 97, 122, 123] (LE: 3).

The benefits and risks of immediate and delayed RC should be discussed with patients. Individual additional prognostic factors in T1 G3 tumours mentioned in Section 6.1, as well as pathologic parameters (particularly LVI and unusual histologies) mentioned in Section 4.6, should be considered.

Early RC is strongly recommended in patients with BCG-refractory tumours, as mentioned above. A delay in RC might lead to decreased disease-specific survival [228] (LE: 3). In patients in whom RC is performed at the time of pathological NMIBC, the 5-year disease-free survival rate exceeds 80% [229-233] (LE: 3).

Table 7.3: Treatment recommendations in Ta, T1 tumours and CIS according to risk stratification

Risk category	Definition	Treatment recommendation
Low-risk tumours	Primary, solitary, Ta, LG/G1, < 3 cm, no CIS	One immediate instillation of chemotherapy.
Intermediate-risk tumours	All cases between categories of low and high risk	One immediate instillation of chemotherapy followed by further instillations, either chemotherapy for a maximum of 1 year or 1-year full-dose BCG.
High-risk tumours	Any of the following: <ul style="list-style-type: none"> • T1 tumours; • HG/G3 tumours; • CIS; • Multiple and recurrent and large (> 3 cm) Ta G1G2 tumours (all these conditions must be present). 	Intravesical full-dose BCG instillations for 1-3 years or cystectomy (in highest-risk tumours).
Subgroup of highest-risk tumours	T1G3 associated with concurrent bladder CIS, multiple and/or large T1G3 and/or recurrent T1G3, T1G3 with CIS in prostatic urethra, unusual histology of urothelial carcinoma, LVI (see Sections 4.6 and 6.2).	Radical cystectomy should be considered in those who refuse RC, intravesical full-dose BCG instillations for 1-3 years.
	BCG failures	Radical cystectomy is recommended.

BCG = bacillus Calmette-Guérin; CIS = carcinoma in situ; GR = grade of recommendation; HG = high-grade; LG = low-grade; LVI = lymphovascular invasion.

Table 7.4: Treatment recommendations for BCG failure and recurrences after BCG

Category	Treatment recommendation	GR
BCG-refractory tumour	1. Radical cystectomy 2. Bladder-preserving strategies in patients unsuitable for cystectomy	B
HG recurrence after BCG	1. Radical cystectomy 2. Repeat BCG course 3. Bladder-preserving strategies	C
Non-HG recurrence after BCG for primary intermediate-risk tumour	1. Repeat BCG or intravesical chemotherapy 2. Radical cystectomy	C

BCG = bacillus Calmette-Guérin; GR = grade of recommendation; HG = high-grade.

7.5 Recommendations for adjuvant therapy in Ta, T1 tumours and for therapy of CIS

	GR
Smokers with confirmed NMIBC should be counselled to stop smoking.	B
The type of further therapy after BCG should be based on the risk groups shown in Tables 6.3 and 7.3.	A
In patients with tumours presumed to be at low- or intermediate risk, one immediate chemotherapy instillation is recommended.	A
In patients with low-risk tumours, one immediate instillation of chemotherapy is recommended as the complete adjuvant treatment.	A
In patients with intermediate-risk tumours, one immediate instillation of chemotherapy should be followed by 1-year full-dose BCG treatment, or by further instillation of chemotherapy for a maximum of 1 year. The final choice should reflect the individual patient's risk of recurrence and progression as well as the efficacy and side effects of each treatment modality.	A
In patients with high-risk tumours, full-dose intravesical BCG for 1-3 years is indicated. The additional beneficial effect of the second and third years of maintenance should be weighed against its added costs and inconvenience.	A
In patients with CIS in the epithelial lining of the prostatic urethra, TUR of the prostate followed by intravesical instillation of BCG can be offered.	C
In patients at highest risk of tumour progression (Table 7.3), immediate radical cystectomy should be considered.	C
In patients with BCG failure, radical cystectomy is indicated.	B
Intravesical chemotherapy	
One immediate instillation of chemotherapy should be administered within 24 hours after TURB.	C
One immediate instillation of chemotherapy should be omitted in any case of overt or suspected intra- or extra-peritoneal perforation (after extensive TURB, or bleeding requiring bladder irrigation).	C
Give clear instructions to the nursing staff to control the free flow of the bladder catheter at the end of the immediate instillation.	C
The optimal schedule of further intravesical chemotherapy instillation and its duration is not defined, but it should not exceed 1 year.	C
If intravesical chemotherapy is given, it is advised to use the drug at its optimal pH and to maintain the concentration of the drug by reducing fluid intake before and during instillation.	B
The length of an individual instillation should be 1-2 hours.	C
BCG intravesical immunotherapy	
Absolute contraindications of BCG intravesical instillation are: <ul style="list-style-type: none"> • during the first 2 weeks after TURB; • in patients with visible haematuria; • after traumatic catheterisation; • in patients with symptomatic urinary tract infection. 	C
The management of side effects after BCG intravesical instillation should reflect their type and grade (Table 7.1).	C

BCG = *bacillus Calmette-Guérin*; CIS = *carcinoma in situ*; GR = grade of recommendation;

MMC = *mitomycin C*; TUR = *transurethral resection*; TURB = *transurethral resection of the bladder*.

8. FOLLOW-UP OF PATIENTS WITH NMIBC

As a result of the risk of recurrence and progression, patients with NMIBC need to be followed up. However, the frequency and duration of cystoscopy and imaging should reflect the individual patient's degree of risk. Using risk tables (see Tables 6.1 and 6.2), the short- and long-term risks of recurrence and progression in individual patients may be predicted and the follow-up schedule adapted accordingly [122, 123].

When planning the follow-up schedule and methods, the following aspects should be considered:

- The prompt detection of muscle-invasive and HG/G3 non-muscle-invasive recurrence is crucial because a delay in diagnosis and therapy can be life-threatening.
- Tumour recurrence in the low-risk group is nearly always low stage and LG/G1. Small, Ta LG/G1 papillary recurrence does not present an immediate danger to the patient and early detection is not essential for successful therapy [234-238] (LE: 2b). Fulguration of small papillary recurrences on

- an outpatient basis could be a safe option that reduces the therapeutic burden [90] (LE: 3). Some authors have even defended temporary surveillance in selected cases [237-239] (LE: 3).
- The first cystoscopy after TURB at 3 months is a very important prognostic indicator for recurrence and progression [128, 134, 240-242] (LE: 1a). Therefore, the first cystoscopy should always be performed 3 months after TURB in all patients with Ta, T1 tumours and CIS.
- In tumours at low-risk, the risk of recurrence after 5 recurrence-free years is low [241] (LE: 3). Discontinuation of cystoscopy or its replacement with less-invasive methods can be considered [242].
- In tumours originally intermediate- or high-risk, recurrences after 10 years tumour-free are not unusual [243] (LE: 3). Therefore, life-long follow-up is recommended [242].
- The follow-up strategy must reflect the risk of extravesical recurrence (prostatic urethra in men and UUT)
- The risk of UUT recurrence increases in patients with multiple- and high-risk tumours [55] (LE: 3).
- Positive urine test results have a positive impact on the quality of performed follow-up cystoscopy [82] (LE: 1b). It supports the adjunctive role of urine tests during follow-up.

No non-invasive method has been proposed that can replace endoscopy and follow-up is therefore based on regular cystoscopy (see Section 5.7). There is a lack of randomized studies that have investigated the possibility of safely reducing the frequency of follow-up cystoscopy.

As CIS is often not visible, multiple biopsies may be necessary in selected cases to confirm the efficacy of intravesical treatment in patients treated for CIS [83].

The following recommendations are based mostly on retrospective data.

8.1 Guidelines for follow-up in patients after TURB of NMIBC

	GR
The follow-up of Ta, T1 tumours and CIS is based on regular cystoscopy.	A
Patients with low-risk Ta tumours should undergo cystoscopy at 3 months. If negative, subsequent cystoscopy is advised 9 months later, and then yearly for 5 years.	C
Patients with high-risk tumours should undergo cystoscopy and urinary cytology at 3 months. If negative, subsequent cystoscopy and cytology should be repeated every 3 months for a period of 2 years, and every 6 months thereafter until 5 years, and then yearly.	C
Patients with intermediate-risk Ta tumours should have an in-between follow-up scheme using cystoscopy and cytology, which is adapted according to personal and subjective factors.	C
Regular (yearly) upper tract imaging (CT-IVU or IVU) is recommended for high-risk tumours.	C
Endoscopy under anaesthesia and bladder biopsies should be performed when office cystoscopy shows suspicious findings or if urinary cytology is positive.	B
Consider R-biopsies or biopsies with PDD after intravesical treatment (at 3 or 6 months) in patients with CIS.	C
During follow-up in patients with positive cytology and no visible tumour in the bladder, R-biopsies or biopsies with PDD (if equipment is available) and investigation of extravesical locations (CT urography, prostatic urethra biopsy) are recommended.	B

CIS = carcinoma in situ; CT-IVU = computed tomography intravenous urography; GR = grade of recommendation; IVU = intravenous urography; PDD = photodynamic diagnosis; R-biopsies = random biopsies.

10. CONFLICT OF INTEREST

All members of the Non-Muscle-Invasive Bladder Cancer guidelines working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: <http://www.uroweb.org/guidelines/>. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

1. INTRODUCTION

Upper tract urothelial carcinoma (UTUC) are relatively uncommon compared to bladder cancer, but 60% of UTUCs are invasive at diagnosis.

1.1 Panel composition

The European Association of Urology (EAU) Guidelines Panel on UTUC consists of an international multidisciplinary group of clinicians, including a pathologist and a statistician. Members of this panel have been selected based on their expertise and to represent the professionals treating patients suspected of harbouring urothelial carcinoma.

All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website.

1.2 Available publications

A quick reference document (Pocket guidelines) is available in print and in a number of versions for mobile devices, presenting the main findings of the UTUC Guidelines. These are abridged versions which may require consultation together with the full text versions. Several scientific publications are available as are a number of translations of all versions of the EAU UTUC Guidelines. All documents are accessible through the EAU website Uroweb: <http://www.uroweb.org/guidelines/online-guidelines/>.

1.3 Publication history & summary of changes

The first EAU guidelines on UTUC were published in 2011. The current 2015 EAU guidelines on UTUC present an update of the 2014 version, and provide evidence-based information for clinical management of UTUC.

1.3.1 Summary of changes

A detailed overview of changes for this 2015 print version is posted online.

The literature for the complete document has been assessed and updated, whenever relevant;

Key changes for this 2015 print:

- New algorithms have been included:
 - Fig. 3.1: Selection of patients with UTUC for hereditary screening from first medical interview.
 - Fig. 6.1: UTUC prognostic factors;
 - Fig. 6.2: Risk stratification of UTUC (table presentation in the 2014 print version);
 - Fig. 7.1: Proposed flowchart for the management of UTUC was amended.

Recommendations have been rephrased and added to throughout the current document.

In Table 7.1. Guidelines for kidney sparing management of low-risk UTUC, the open surgical approach options have been expanded, not resulting in a change in the grade of recommendation (GR).

Surgical open approach	
<i>Renal pelvis or calyces:</i> Partial pyelectomy or partial nephrectomy is seldom indicated.	C
<i>Ureter - Mid & proximal:</i> Ureteroureterostomy is indicated for tumours that cannot be removed completely endoscopically.	C
<i>Ureter - Distal:</i> Complete distal ureterectomy and neocystostomy are indicated for tumours in the distal ureter that cannot be removed completely endoscopically.	C

2. METHODS

2.1 Data identification

Medline was searched for urothelial malignancies and UTUC management using combinations of the following: *urinary tract cancer, urothelial carcinoma, upper urinary tract, renal pelvis, ureter, chemotherapy, nephroureterectomy, adjuvant treatment, neoadjuvant treatment, recurrence, risk factors, nomogram, and survival*, with a November 2013 cut-off. Articles were selected using the following criteria: evolution of concepts, intermediate- and long-term clinical outcomes, study quality, and relevance. To facilitate evaluation of information quality, level of evidence (LE) and grade of recommendation (GR) were inserted according to evidence-based medicine (EBM) [1].

In this 2015 EAU Guidelines compilation, all standard information on levels of evidence (LE) and grading of recommendations (GR) has been taken out of the individual guidelines topics for the sake of brevity. This information is included in the introductory section of this print.

2.2 Review

This document was subjected to double-blind peer review prior to publication.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

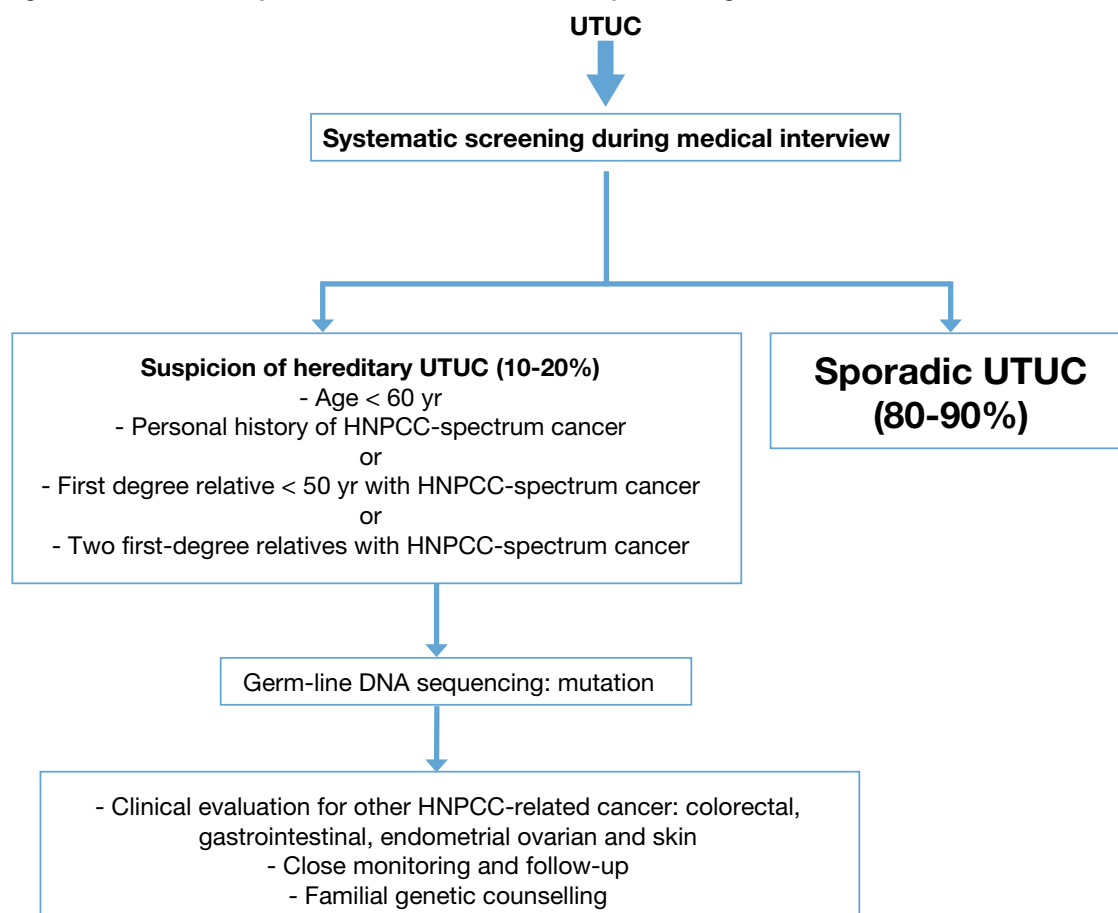

3.1 Epidemiology

Urothelial carcinomas (UCs) are the fourth most common tumours [2]. They can be located in the lower (bladder and urethra) or upper (pyelocaliceal cavities and ureter) urinary tract. Bladder tumours account for 90-95% of UCs and are the most common malignancy of the urinary tract [3]. However, UTUCs are uncommon and account for only 5-10% of UCs [2, 4], with an estimated annual incidence in Western countries of ~2 cases per 100,000 inhabitants. Pyelocaliceal tumours are about twice as common as ureteral tumours. In 17% of cases, concurrent bladder cancer is present [5]. Recurrence in the bladder occurs in 22-47% of UTUC patients [6-8], compared with 2-6% in the contralateral upper tract [9, 10].

Sixty percent of UTUCs are invasive at diagnosis compared with 15-25% of bladder tumours [11, 12]. UTUCs have a peak incidence in people aged 70-90 years and are three times more common in men [13, 14].

Familial/hereditary UTUCs are linked to hereditary non-polyposis colorectal carcinoma (HNPCC) [15], which can be screened during interview (Figure 3.1) [16]. Patients should undergo DNA sequencing to identify hereditary cancers misclassified as sporadic [15, 17].

Figure 3.1: Selection of patients with UTUC for hereditary screening from first medical interview

HNPCC = hereditary non-polyposis colorectal carcinoma.

3.2 Risk factors

Many environmental factors contribute to UTUC development [18, 19]. Tobacco exposure increases the relative risk from 2.5 to 7 [18, 19]. Historically, UTUC 'amino tumours' were related to occupational exposure to carcinogenic aromatic amines, including benzidine and β -naphthalene - both of which have been banned since the 1960s in most industrialised countries.

Upper tract urothelial carcinoma is mostly secondary to an amino tumour of the bladder. The average duration of exposure needed to develop UTUC is ~7 years, with a latency of ~20 years following termination of exposure. The odds ratio of developing UC after exposure to aromatic amines is 8.3 [19, 20]. Upper urinary tract tumours caused by phenacetin consumption almost disappeared after the product was banned in the 1970s [19].

Several studies have revealed the carcinogenic potential of aristolochic acid contained in *Aristolochia fangchi* and *Aristolochia clematis*. The aristolochic acid derivative d-aristolactam causes a specific mutation in the p53 gene at codon 139, which occurs mainly in patients with nephropathy due to Chinese herbs or Balkan endemic nephropathy, who present with UTUC [19, 21, 22].

There is a high incidence of UTUC in Taiwan, especially on the South-west coast which represents 20-25% of UCs in the region [19, 22]. There is a possible association of UTUC with blackfoot disease and arsenic exposure in drinking water in this population [19, 22, 23].

Differences in the ability to counteract carcinogens may contribute to host susceptibility to UTUC. Some genetic polymorphisms are associated with an increased risk of cancer or faster disease progression, which introduces variability in the inter-individual susceptibility to the risk factors previously mentioned. UTUC may share some risk factors or molecular disruption pathways with bladder urothelial carcinoma. Only two UTUC-specific polymorphisms have been reported [24, 25].

3.2 Histology and classification

3.2.1 Histological types

There are morphological variants of UTUC that are more often observed in urothelial kidney tumours. These variants always correspond to high-grade tumours that are associated with one of the following [26]: micropapillary, clear cell, neuroendocrine or lymphoepithelial variants [27, 28]. Collecting-duct carcinoma can have similar characteristics to UTUC because of its common embryological origin [29].

UTUC with pure non-urothelial histology is an exception [30, 31] but variants are present in ~25% of cases [26, 32]. Squamous cell carcinoma of the upper urinary tract represents < 10% of pyelocaliceal tumours and is even rarer within the ureter. Squamous cell carcinoma of the urinary tract is associated with chronic inflammatory and infectious diseases arising from urolithiasis [27, 28]. Other histological subtypes are adenocarcinoma (< 1%), small cell carcinoma, and sarcoma.

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Classification

The classification and morphology of UTUC and bladder carcinoma are similar [11]. It is possible to distinguish between non-invasive papillary tumours (papillary urothelial tumours of low malignant potential, and low-grade and high-grade papillary UC), flat lesions (carcinoma *in situ* [CIS]), and invasive carcinoma.

4.2 Tumour Node Metastasis staging

The Tumour Node Metastasis (TNM) classification is shown in Table 4.1 [33]. The regional lymph nodes that should be considered are the hilar, abdominal para-aortic, and paracaval nodes, and, for the ureter, the intrapelvic nodes. Laterality does not affect N classification.

Renal pelvic pT3 subclassification may discriminate between microscopic infiltration of the renal parenchyma (pT3a) and macroscopic infiltration or invasion of peripelvic adipose tissue. pT3a and pT3b have been suggested as a subclassification [26, 34, 35]. pT3b UTUC is more likely to have aggressive pathology and higher risk of recurrence [26, 34].

Table 4.1: TNM classification 2009 for upper tract urothelial carcinoma

T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
Tis	Carcinoma <i>in situ</i>
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades muscle
T3	(Renal pelvis) Tumour invades beyond muscularis into peripelvic fat or renal parenchyma (Ureter) Tumour invades beyond muscularis into periureteric fat
T4	Tumour invades adjacent organs or through the kidney into perinephric fat
N - Regional lymph nodes	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Metastasis in a single lymph node 2 cm or less in the greatest dimension
N2	Metastasis in a single lymph node more than 2 cm but not more than 5 cm in the greatest dimension or multiple lymph nodes, none more than 5 cm in greatest dimension
N3	Metastasis in a lymph node more than 5 cm in greatest dimension
M - Distant metastasis	
M0	No distant metastasis
M1	Distant metastasis

4.3 Tumour grade

Until 2004, the World Health Organization (WHO) classification of 1973 was used most often, which distinguished only three grades (G1-G3) [36, 37]. The recent 2004 WHO classification considers histological data to distinguish non-invasive tumours: papillary urothelial neoplasia of low malignant potential, and low-grade and high-grade carcinomas (low grade vs. high grade). Only few tumours of low malignant potential are found in the upper urinary tract [27, 28].

5. DIAGNOSIS

5.1 Symptoms

Diagnosis of UTUC may be fortuitous or related to exploration of symptoms, which are generally limited [38]. The most common symptom is visible- or non-visible haematuria (70-80%) [39]. Flank pain occurs in 20-40% of cases, and a lumbar mass is present in 10-20% [40, 41]. Systemic symptoms (including anorexia, weight loss, malaise, fatigue, fever, night sweats, or cough) associated with UTUC should prompt more rigorous metastatic evaluation [40, 41].

5.2 Diagnosis

5.2.1 Imaging

5.2.1.1 Computed tomography urography

Computed tomography urography (CTU) has the highest diagnostic accuracy for high-risk patients [39]. The sensitivity of CTU for UTUC is 0.67-1.0 and the specificity is 0.93-0.99 [42-49].

Computed tomography urography acquires at least one image series during the excretory phase, usually 10-15 min, following administration of intravenous contrast medium [50]. Rapid acquisition of thin sections allows for high-resolution isotropic images that can be viewed in multiple planes to assist with diagnosis without loss of resolution [51, 52].

Flat lesions are not detectable unless they exert a mass effect or cause urothelial thickening [53].

The secondary sign of hydronephrosis upon imaging of UTUC is associated with advanced disease and poor oncological outcome [50, 54, 55]. The presence of enlarged lymph nodes is highly predictive of metastasis in UTUC [56].

5.2.1.2 Magnetic resonance imaging

Magnetic resonance urography (MRU) is indicated in patients who cannot undergo CTU, usually when radiation

or iodinated contrast media are contraindicated [57]. The sensitivity of MRU is 75% after contrast injection for tumours < 2 cm [57]. The use of MRU with gadolinium-based contrast media should be limited in patients with severe renal impairment (< 30 mL/min creatinine clearance), due to the risk of nephrogenic systemic fibrosis.

Computed tomography urography is generally preferred over MRU for diagnosing UTUC.

5.2.2 Cystoscopy and urinary cytology

Positive urine cytology is highly suggestive of UTUC when bladder cystoscopy is normal, provided that no CIS in the bladder or prostatic urethra CIS has been detected [11, 58]. Cytology is less sensitive for UTUC than bladder tumours and it should be performed *in situ* in the renal cavities [59]. Retrograde ureteropyelography remains an option to detect upper urinary tract tumours [43, 60]. Urinary cytology of the renal cavities and ureteral lumina is preferable before application of contrast agent for retrograde ureteropyelography, because it may cause deterioration of cytological specimens [59, 60].

The sensitivity of fluorescence *in situ* hybridisation (FISH) for molecular abnormalities characteristic of UTUCs parallels its performance in bladder cancer. However, its use may be limited by the preponderance of low-grade recurrent disease in the population undergoing surveillance and minimally invasive therapy for UTUCs [61, 62]. FISH appears to have a limited value for surveillance of UTUCs [61, 62].

5.2.3 Diagnostic ureteroscopy

Flexible ureteroscopy is used to visualise and biopsy the ureter, renal pelvis and collecting system. Such ureteroscopic biopsies can determine tumour grade in 90% of cases with a low false-negative rate, regardless of sample size [63]. Undergrading may occur from diagnostic biopsy, making intensive follow-up necessary if renal-sparing treatment is selected [64]. Ureteroscopy also facilitates selective ureteral sampling for cytology *in situ* [60, 65, 66].

Flexible ureteroscopy is especially useful for diagnostic uncertainty, when conservative treatment is considered, or in patients with a solitary kidney. Ureteroscopy and biopsy should be performed in preoperative assessment of UTUC. Combining ureteroscopic biopsy grade, imaging findings such as hydronephrosis, and urinary cytology, may help decide between radical nephroureterectomy (RNU) and endoscopic treatment [65, 67].

Technical developments in flexible ureteroscopes and the use of novel imaging techniques improve visualisation and diagnosis of flat lesions. Narrow-band imaging is the most promising technique but results are preliminary [67, 68]. Table 5.1 lists the recommendations for diagnosis.

Table 5.1: Diagnostic guidelines for upper tract urothelial carcinoma

Recommendations	GR
Urinary cytology should be performed as part of a standard diagnostic work-up.	A
A cystoscopy should be done to rule out concomitant bladder tumour.	A
CTU must be part of the diagnostic work-up.	A
Diagnostic ureteroscopy and biopsy should be performed, certainly in cases where additional information will impact treatment decisions.	C
Retrograde ureteropyelography is an optional tool for the detection of UTUC.	C

CTU = computed tomography urography; GR = grade of recommendation.

6. PROGNOSIS

6.1 Prognostic factors

Upper tract urothelial carcinomas that invade the muscle wall usually have poor prognosis. The 5-year specific survival is < 50% for pT2/pT3 and < 10% for pT4 [68-70]. The main prognostic factors are briefly listed below; Figure 6.1 presents an exhaustive list.

Figure 6.1: Upper tract urothelial carcinoma - Prognostic factors

ASA = American Society of Anesthesiologists; BMI = body mass index; ECOG = Eastern Cooperative Oncology Group.

6.1.1 Preoperative factors

6.1.1.1 Age and sex

Sex is no longer considered an independent prognostic factor that influences UTUC mortality [13, 70, 71]. Older age at the time of RNU is independently associated with decreased cancer-specific survival [70, 72] (LE: 3). Many elderly patients can be cured with RNU [72], suggesting that age alone is an inadequate indicator of outcome [72, 73]. Advanced age is linked with survival but it does not have to be considered as an absolute exclusion criterion for decision of treatment of potentially curable UTUC.

6.1.1.2 Ethnicity

One multicentre study did not show any difference between races [74] but population-based studies have indicated that African-American patients have worse outcomes compared to other racial groups [73] (LE: 3).

6.1.1.3 Tobacco consumption

Being a smoker at diagnosis increases the risk for poor oncological outcomes [75-77] and recurrence within the bladder [78] (LE: 3).

6.1.1.4 Tumour location

Initial location of the tumour within the upper urinary tract is a prognostic factor [79-81] (LE: 3). After adjustment for tumour stage, ureteral and multifocal tumours have a worse prognosis than renal pelvic tumours [70, 80-83].

6.1.1.5 Surgical waiting time

A delay between diagnosis and tumour removal may increase the risk of disease progression. The cut-off for

removal is controversial and ranges between 30 days and 3 months [84-87] (LE: 3).

6.1.1.6 *Other*

The American Society of Anesthesiologists (ASA) score also significantly correlates with cancer-specific survival after RNU [88] (LE: 3), but Eastern Cooperative Oncology Group (ECOG) performance status correlates only with overall survival [89]. Obesity and higher body mass index adversely affect cancer-specific outcomes in UTUCs [90] (LE: 3).

6.1.2 **Post-operative factors**

6.1.2.1 *Tumour stage and grade*

The primary recognised prognostic factors are tumour stage and grade [65, 70, 91, 92].

6.1.2.2 *Lymph node involvement*

Extranodal extension is a powerful predictor of clinical outcomes in UTUCs and positive lymph node metastases [93]. Lymph node dissection (LND) associated with RNU allows for optimal tumour staging [94, 95] (LE: 3). Lymph node invasion is an important prognostic factor, indicating metastatic spread to the lymph nodes.

6.1.2.3 *Lymphovascular invasion*

Lymphovascular invasion is present in ~20% of UTUCs and is an independent predictor of survival [96, 97]. Lymphovascular invasion status should be systematically included and specifically reported in the pathological reports of all RNU specimens [96, 98] (LE: 3).

6.1.2.4 *Surgical margins*

Positive surgical margin after RNU is a significant factor for developing UTUC metastases. Pathologists should look for and report positive margins at the level of ureteral transection, bladder cuff, and around the tumour if it is T > 2 [99] (LE: 3).

6.1.2.5 *Pathological factors*

Extensive tumour necrosis (> 10% of the tumour area) is an independent prognostic predictor in patients who undergo RNU [100, 101] (LE: 3). The tissue architecture of UTUC is associated with prognosis after RNU. Sessile growth pattern is associated with the worst outcome [102, 103] (LE: 3). Concomitant CIS in organ-confined UTUC, and a history of bladder CIS are associated with a higher risk of recurrence and cancer-specific mortality [104-106] (LE: 3). Similar to lower tract UC, concomitant CIS is an independent predictor of worse outcomes in organ-confined disease [107].

6.2 **Molecular markers**

Several studies have investigated the prognostic impact of markers related to cell adhesion (E-cadherin and CD24), cell differentiation (Snail and epidermal growth factor receptor), angiogenesis (hypoxia-inducible factor-1 α and metalloproteinases), cell proliferation (Ki67), epithelial-mesenchymal transition (Snail), mitosis (Aurora-A), apoptosis (Bcl-2 and survivin), vascular invasion (RON), and c-met protein (MET) [70, 108-112]. Microsatellite instability (MSI) is an independent molecular prognostic marker [113]. MSI can help detect germline mutations and hereditary cancers [15].

The rarity of UTUC means that the main limitations of the above studies were their retrospective nature and small sample size. None of the markers have fulfilled the criteria necessary to support their introduction in daily clinical decision making.

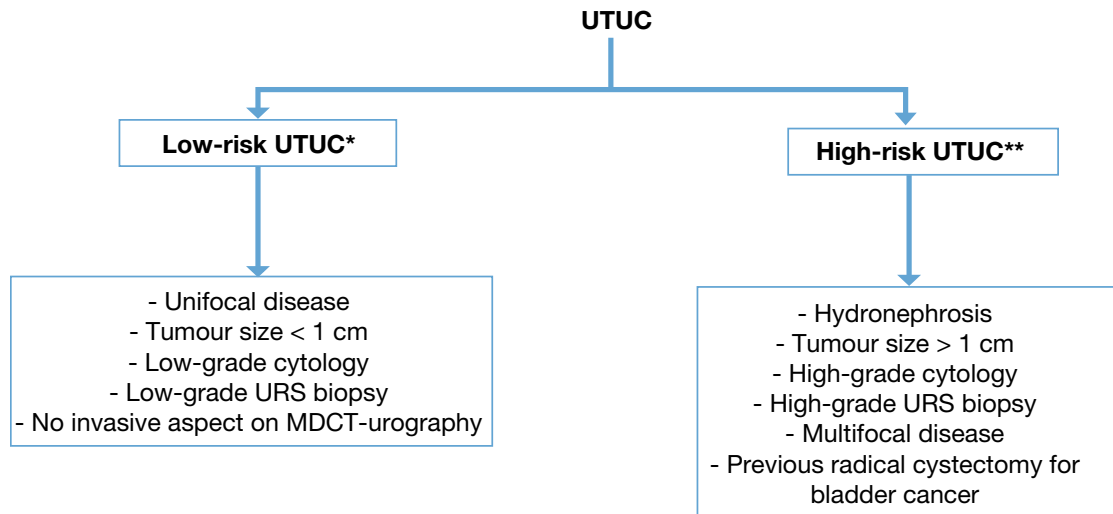

6.3 **Predictive tools**

Accurate predictive tools are rare for UTUC. There are two models in a preoperative setting: one for prediction LND of locally advanced cancer that could guide the extent of LND at the time of RNU [114]; and one for selection of non-organ-confined UTUC that is likely to benefit from nephroureterectomy [115]. Four nomograms predict survival rates postoperatively based on standard pathological features [116-119].

6.4 **Risk stratification**

As with NMIBC, it is necessary to 'risk stratify' UTUC before treatment to identify tumours that are more suitable for kidney-sparing treatment than radical extirpative surgery [120] (Figure 6.2).

Figure 6.2: Risk stratification of upper tract urothelial carcinoma

* All of these factors need to be present

** Any of these factors need to be present

MDCT = multidetector-row computed tomography; URS = ureterorenoscopy.

7. DISEASE MANAGEMENT

7.1. Localised disease

7.1.1 Kidney-sparing surgery

Conservative management of UTUC can be discussed in low-risk cases when the contralateral kidney is functional [121-123]. Kidney-sparing surgery for low-risk UTUC (Table 7.1) allows sparing the morbidity associated with open radical surgery, without compromising oncological outcomes and kidney function [124]. In addition, it can also be considered in all imperative cases (i.e.; renal insufficiency or solitary functional kidney) (LE: 3).

7.1.1.1 Ureteroscopy

Endoscopic ablation can be considered in highly selected cases and in the following situations [125, 126]:

- Laser generator [127] and pliers are available for biopsies [126, 128] (LE: 3);
- Flexible rather than rigid ureteroscope;
- The patient is informed of the need for closer, more stringent, surveillance;
- Complete tumour resection is strongly advocated.

However, there is a risk of understaging and undergrading with pure endoscopic management.

7.1.1.2 Percutaneous access

Percutaneous management can be considered for low-grade or non-invasive UTUCs in the renal cavities [126, 129, 130] (LE: 3). This may be offered for low-grade tumours in the lower caliceal system that are inaccessible or difficult to manage by flexible ureteroscopy. This approach is being used less due to the availability of enhanced materials and advances in distal-tip deflection of recent ureteroscopes [126, 129, 130].

7.1.1.3 Segmental resection

Segmental ureteral resection with wide margins provides adequate pathological specimens for staging and grading, while preserving the ipsilateral kidney.

- Ureteroureterostomy is indicated for non-invasive, low-grade tumours of the proximal- or mid-ureter that cannot be removed completely endoscopically, and for high-grade or invasive tumours when renal-sparing surgery for renal function preservation is a goal.
- High-grade tumours of the proximal- or mid-ureter should undergo RNU with bladder cuff excision. Complete distal ureterectomy +/- neocystostomy are indicated for non-invasive, low-grade tumours

in the distal ureter that cannot be removed completely endoscopically, and for high-grade, locally-invasive tumours [131-133] (LE: 3).

- Segmental resection of the iliac and lumbar ureter is associated with greater failure than for the distal pelvic ureter [131-133].
- Open resection of tumours of the renal pelvis or calices has almost disappeared.
- Resection of pyelocaliceal tumours is technically difficult and has higher recurrence than ureteral tumours.

Table 7.1: Guidelines for kidney-sparing management of low-risk upper tract urothelial carcinoma

Indications for endourological management	GR
Unifocal tumour.	B
Tumour < 1 cm.	B
Low-grade tumour.	B
No evidence of infiltrative lesion on CTU.	B
Understanding of close follow-up.	B
Techniques used according to location:	
• Laser should be used for endoscopic treatment.	C
• Flexible is preferable to rigid ureteroscopy: renal pelvis, distal-, mid- and proximal ureter.	C
• Percutaneous approach remains an option for low grade tumours not accessible by ureteroscopic approach.	C
Surgical open approach	
<i>Renal pelvis or calyces:</i> Partial pyelectomy or partial nephrectomy is seldom indicated.	C
<i>Ureter - Mid & proximal:</i> Ureteroureterostomy is indicated for tumours that cannot be removed completely endoscopically.	C
<i>Ureter - Distal:</i> Complete distal ureterectomy and neocystostomy are indicated for tumours in the distal ureter that cannot be removed completely endoscopically.	C

CTU = computed tomography urography; GR = grade of recommendation.

7.1.1.4 Adjuvant topical agents

The antegrade instillation of bacillus Calmette-Guérin (BCG) vaccine or mitomycin C in the upper urinary tract by percutaneous nephrostomy via a three-valve system open at 20 cm (after complete tumour eradication) is feasible after conservative treatment of UTUC or for treatment of CIS [134] (LE: 3). Retrograde instillation through a ureteric stent is also used but it can be dangerous due to possible ureteric obstruction and consecutive pyelovenous influx during instillation/perfusion. The reflux obtained from a double-J stent has been used [135], but is not advisable since it often does not reach the renal pelvis.

7.1.2 Radical nephroureterectomy

Open RNU with bladder cuff excision is the standard for high-risk UTUC, regardless of tumour location [12] (LE: 3). Radical nephroureterectomy must comply with oncological principles, which consist of preventing tumour seeding by avoiding entry into the urinary tract during resection [12].

Resection of the distal ureter and its orifice is performed because there is a considerable risk of tumour recurrence in this area. After removal of the proximal ureter, it is difficult to image or approach it by endoscopy. Removal of the distal ureter and bladder cuff is beneficial after RNU [121, 136, 137]. Regardless of the technique, the surgeon must be confident that the bladder is closed appropriately.

Several techniques have been considered to simplify distal ureter resection, including pluck technique, stripping, transurethral resection of the intramural ureter, and intussusception [9, 137, 138]. Except for ureteral stripping, none of these techniques is inferior to bladder cuff excision [72-74, 80] (LE: 3). Endoscopy is associated with a higher risk of subsequent bladder recurrence [139, 140].

7.1.2.1 Laparoscopic radical nephroureterectomy

Retroperitoneal metastatic dissemination and dissemination along the trocar pathway following manipulation of large tumours in a pneumoperitoneal environment have been reported in only few cases [141, 142].

Several precautions are needed with pneumoperitoneum because it may increase tumour spillage:

- Entering the urinary tract should be avoided;
- Direct contact between instruments and tumour should be avoided;

- Laparoscopic RNU must take place in a closed system. Morcellation of the tumour should be avoided and an endobag is necessary for tumour extraction;
- The kidney and ureter must be removed en bloc with the bladder cuff;
- Invasive or large (T3/T4 and/or N+/M+) tumours are contraindications for laparoscopic RNU until proven otherwise.

Safety of laparoscopic RNU has been demonstrated. There is a tendency towards equivalent oncological outcomes after laparoscopic or open RNU [142-148] (LE: 3).

Only one prospective randomised study has shown that laparoscopic RNU is not inferior to open RNU for non-invasive UTUC [149] (LE: 2). Oncological outcomes after RNU have not changed significantly over the past three decades despite staging and surgical refinements [150] (LE: 3).

7.1.2.2 Lymph node dissection

Anatomical sites of LND have not been clearly defined. The LND template is likely to have a greater impact on patient survival than the number of lymph nodes removed [127].

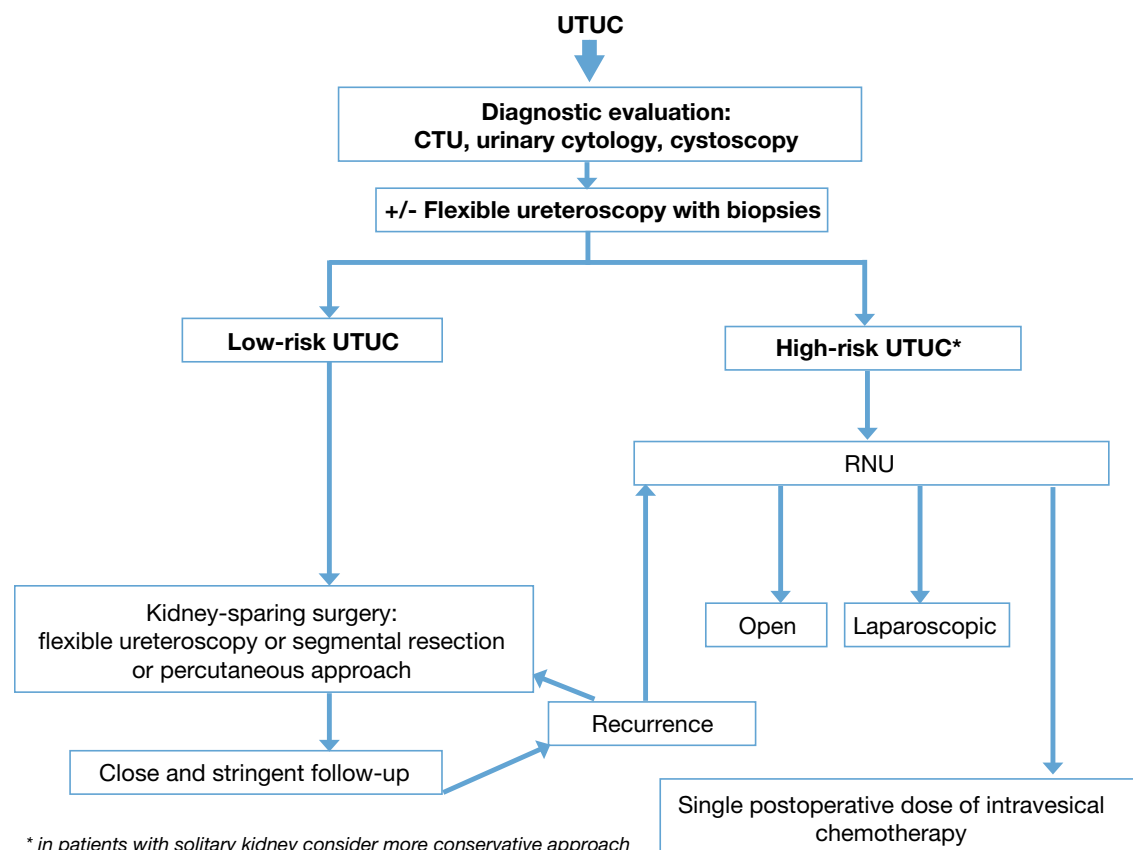

Lymph node dissection appears to be unnecessary in cases of TaT1 UTUC because lymph node retrieval is reported in only 2.2% of T1 versus 16% of pT2-4 tumours [95]. An increase in the probability of lymph-node-positive disease is related to pT classification [95]. However, it is likely that the true rate of node-positive disease has been under-reported because these data are retrospective.

It is not possible to standardise indication or extent of LND. Lymph node dissection can be achieved following lymphatic drainage as follows: LND medial to the ureter in ureteropelvic tumour, retroperitoneal LND for higher ureteral tumour and/or tumour of the renal pelvis (i.e. right side: border vena cava or right side of the aorta; and left side: border aorta) [94, 95, 127].

7.1.2.3 Chemotherapy

One prospective randomised study has demonstrated that a single postoperative dose of intravesical mitomycin on the day of catheter removal reduces the risk of bladder tumour within the first year post-RNU [151] (LE: 2). This therapeutic strategy was confirmed in another prospective trial with pirarubicin [152] and in a meta-analysis [153]. Management is outlined in Figure 7.1.

Figure 7.1: Proposed flowchart for the management of upper tract urothelial carcinoma

CTU = computed tomography urography; RNU = radical nephroureterectomy.

Table 7.2: Guidelines for radical nephroureterectomy in upper tract urothelial carcinoma

Indications for RNU	GR
Suspicion of infiltrating UTUC on imaging.	B
High-grade tumour (urinary cytology).	B
Multifocality (with two functional kidneys).	B
Non-invasive but large (> 1 cm) UTUC.	B
Techniques for RNU	
Open and laparoscopic access has equivalent efficacy in T1-T2/N0 tumours.	B
Bladder cuff removal is imperative.	A
Several techniques for bladder cuff excision are acceptable, except stripping.	C
Lymphadenectomy is recommended for invasive UTUC.	C
Postoperative instillation is recommended after RNU to avoid bladder recurrence.	B

GR = grade of recommendation; RNU = radical nephroureterectomy.

7.2 Advanced disease

7.2.1 Radical nephroureterectomy

There are no benefits of RNU in metastatic disease, although it can be considered as palliative [12, 95] (LE: 3).

7.2.2 Systemic chemotherapy

Upper tract urothelial carcinomas are urothelial tumours; therefore, platinum-based chemotherapy is expected to have similar efficacy as in bladder cancer. However, there are currently insufficient data for recommendations.

There are several platinum-based regimens [154], but the risk of impaired postoperative function means that neoadjuvant chemotherapy is only optional. Not all patients can receive chemotherapy because of comorbidity and impaired renal function after radical surgery. Chemotherapy-related toxicity, particularly nephrotoxicity from platinum derivatives, may significantly reduce survival in patients with postoperative renal dysfunction [155, 156].

There were no adverse effects of neoadjuvant chemotherapy for UTUCs in the only study published to date [157], although survival data need to mature and longer follow-up is awaited.

Adjuvant chemotherapy can achieve a recurrence-free rate of $\leq 50\%$ [158, 159]. After a recent comprehensive search of studies examining the role of chemotherapy for UTUC, there appears to be an overall survival and disease-free survival benefit for cisplatin-based adjuvant chemotherapy [160] (LE: 3). However, it is challenging to make a definitive statement until further evidence from an ongoing prospective trial is available [161].

7.2.3 Radiotherapy

Radiotherapy is no longer relevant, either alone or as an adjunct to chemotherapy [162, 163] (LE: 3).

8. FOLLOW-UP

The risk of recurrence and death evolves over the follow-up after surgery [164]. Stringent follow-up (Table 6) is mandatory to detect metachronous bladder tumours, local recurrence, and distant metastases. When RNU is performed, local recurrence is rare and the risk of distant metastases is directly related to the risk factors listed previously. The rate of bladder recurrence after treatment of primary UTUC is 22-47% [6, 8].

Surveillance regimens are based on cystoscopy and urinary cytology for ≥ 5 years [6-8]. Bladder recurrence should not be considered as distant recurrence. When conservative treatment is performed, the ipsilateral upper urinary tract requires careful follow-up due to the high risk of recurrence [122, 128, 165]. Despite endourological improvements, follow-up after conservative therapy is difficult, and frequent, repeated endoscopic procedures are necessary.

Table 8.1: Guidelines for follow-up of upper tract urothelial carcinoma patients after initial treatment

After RNU, ≥ 5 years	GR
<i>Non-invasive tumour</i>	
• Cystoscopy/urinary cytology at 3 months and then yearly.	C
• CT every year	C
<i>Invasive tumour</i>	
• Cystoscopy/urinary cytology at 3 months and then yearly.	C
• CT urography every 6 months over 2 years and then yearly.	C
After conservative management, ≥ 5 years	
• Urinary cytology and CTU at 3 and 6 months, and then yearly.	C
• Cystoscopy, ureteroscopy and cytology <i>in situ</i> at 3 and 6 months, and then every 6 months over 2 years, and then yearly.	C

CTU = computed tomography urography; GR = grade of recommendation; RNU = radical nephroureterectomy.

1. INTRODUCTION

1.1 Aims and scope

The European Association of Urology (EAU) Guidelines Panel for Muscle-invasive and Metastatic Bladder Cancer (MIBC) has prepared these guidelines to help urologists assess the evidence-based management of MIBC and to incorporate guideline recommendations into their clinical practice.

Separate EAU guidelines documents are available addressing upper urinary tract tumours [1], non-muscle-invasive bladder cancer (Ta, T1 and carcinoma *in situ*) [2], and primary urethral carcinomas [3].

1.2 Panel Composition

The EAU Guidelines Panel consists of an international multidisciplinary group of experts from the fields of urology, pathology, radiology and oncology.

All experts involved in the production of this document have submitted potential conflict of interest statements.

1.3 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text versions. Several scientific publications are available (the most recent paper dating back to 2014 [4]), as are a number of translations of all versions of the EAU MIBC Guidelines. All documents are accessible through the EAU website Uroweb: <http://www.uroweb.org/guidelines/online-guidelines/>.

1.4 Publication history and summary of changes

1.4.1 Publication history

The EAU published its first guidelines on bladder cancer in 2000. This document covered both superficial (non-muscle-invasive) bladder cancer and MIBC. Since these conditions require different treatment strategies, it was decided to give each condition its own guidelines, resulting in the first publication of the MIBC guidelines in 2004. This 2015 document presents a limited update of the 2014 version.

1.4.2 Summary of changes

The literature in the complete document has been assessed and updated, whenever relevant.

Key changes for the 2015 publication:

- Section 7.4.2 on timing and delay of cystectomy was revised.
- Section 7.4.4.2.5 on orthotopic neobladder; additional information on female patients has been included.
- A table on the management of neobladder morbidity (Table 7.1) has been added.
- Section 7.6.4 on multimodality bladder-preserving treatment was completely revised.

Recommendations have been rephrased and added to throughout the current document:

3.3.3 Recommendations for the assessment of tumour specimens

<i>Mandatory evaluations</i>
Depth of invasion (categories pT2 vs pT3a, pT3b or pT4);
Margins with special attention paid to the radial margin, prostate, ureter, urethra and peritoneal fat and uterus and vaginal top.
Histological subtype, if it has clinical implications;
Extensive lymph node representation (more than nine);
<i>Optional evaluations</i>
Bladder wall blood vessel invasion;
Pattern of muscle invasion.

7.2.4 Conclusions and recommendations for neoadjuvant chemotherapy

Conclusions	LE
Neoadjuvant chemotherapy has its limitations regarding patient selection, current development of surgical techniques, and current chemotherapy combinations.	3

Conclusions	LE
No conclusive evidence exists as to the optimal extent of LND.	2a

Conclusions	LE
External beam radiotherapy alone should only be considered as a therapeutic option when the patient is unfit for cystectomy or a multimodality bladder-preserving approach.	3
Radiotherapy can also be used to stop bleeding from the tumour when local control cannot be achieved by transurethral manipulation due to extensive local tumour growth.	3

Recommendation	GR
Radiotherapy alone is not recommended as primary therapy for localised bladder cancer.	B

2. METHODS

2.1 Data identification

The recommendations provided in the current guidelines are based on literature searches performed by the expert panel members. A systemic literature search was performed for the systematic review of the role and extent of lymphadenectomy during radical cystectomy for cN0M0 muscle-invasive bladder cancer (see Section 7.4: Radical surgery and urinary diversion [5]).

There is clearly a need for continuous re-evaluation of the information presented in the current guidelines by an expert panel. It must be emphasised that these guidelines contain information for the treatment of individual patients according to a standardised approach.

In this 2015 EAU Guidelines compilation, all standard information on levels of evidence (LE) and grading of recommendations (GR) has been taken out of the individual guidelines topics for the sake of brevity. This information is included in the introductory section of this print.

2.2 Peer review

This document was subjected to double-blind peer review prior to publication.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Bladder cancer (BC) is the ninth most commonly diagnosed cancer worldwide, with more than 380,000 new cases each year and more than 150,000 deaths per year, and an estimated male-female ratio of 3.8:1.0 [6]. At any one time, 2.7 million people have a history of urinary BC [7].

Recently, overall and stage-specific age-adjusted incidence rates of bladder cancer have been analysed in the U.S. (5-year survival and mortality rates between 1973 and 2009). Although the analysis of the Surveillance, Epidemiology and End Results (SEER) database implies some limitations, it is worrying to note that in the last 30 years the mortality rate associated with BC has not changed substantially, highlighting gaps in diagnosis, monitoring and management of these patients [8].

3.2 Aetiology

3.2.1 Tobacco smoking

Tobacco smoking is the most well-established risk factor for BC, causing 50-65% of male cases and 20-30% of female cases [9]. A causal relationship has been established between exposure to tobacco and cancer in

studies in which chance, bias and confounding can be discounted with reasonable confidence [10].

The incidence of BC is directly related to the duration of smoking and the number of cigarettes smoked per day [11]. A meta-analysis looked at 216 observational studies on cigarette smoking and cancer from 1961 to 2003, and the pooled risk estimates for BC demonstrated a significant association for both current and former smokers [12]. Recently, an increase in risk estimates for current smokers relative to never smokers has been described suggesting this could be due to changes in cigarette composition [9]. An immediate decrease in the risk of BC was observed in those who stopped smoking. The reduction was about 40% within 1-4 years of quitting smoking and 60% after 25 years of cessation [11]. Encouraging people to stop smoking would result in the incidence of BC decreasing equally in men and women.

3.2.2 **Occupational exposure to chemicals**

Occupational exposure is the second most important risk factor for BC. Work-related cases have accounted for 20-25% of all BC cases in several series. The substances involved in chemical exposure include benzene derivatives and aryl amines (2-naphthylamine, 4-ABP, 4,4'-methylenedianiline, and o-toluidine), and it is likely to occur in occupations in which dyes, rubbers, textiles, paints, leathers, and chemicals are used [13]. The risk of BC due to occupational exposure to carcinogenic aromatic amines is significantly greater after 10 years or more of exposure; the mean latency period usually exceeds 30 years [14, 15]. The chemicals involved have contributed minimally to the current incidence of BC in Western countries because of strict regulations. Importantly, in recent years, the extent and pattern of occupational exposure have changed because awareness has prompted safety measures, and population-based studies established the occupational attribution for BC in men to be 7.1%, while no such attribution was discernible for women [16, 17].

3.2.3 **Radiotherapy**

Increased rates of secondary bladder malignancies have been reported after external-beam radiotherapy (EBRT) for gynaecological malignancies, with relative risks of 2-4 [18]. In a population cohort study, the standardised incidence ratios for BC developing after radical prostatectomy (RP), EBRT, brachytherapy (BT), and EBRT-BT were 0.99, 1.42, 1.10, and 1.39, respectively, in comparison with the general U.S. population [19]. It has recently been proposed that patients who have received radiotherapy for prostate cancer with modern modalities such as intensity-modulated radiotherapy (IMRT) may have lower rates of in-field bladder- and rectal secondary malignancies [20]. Nevertheless, since longer follow-up data are not yet available, and as BC requires a long period to develop, patients treated with radiation and with a long life-expectancy are at a higher risk of developing BC [20].

3.2.4 **Dietary factors**

Several dietary factors have been considered to be related to BC; however, the links remain controversial. The EPIC study is an on-going multicentre cohort study designed to examine the association between diet, lifestyle and environmental factors and cancer. They found no links between BC and fluid intake, red meat, vegetable and fruit consumption, and only recently they have described an inverse association between dietary intake of flavonols and lignans and the risk of BC, in particular aggressive tumours [21].

3.2.5 **Bladder schistosomiasis and chronic urinary tract infection**

Bladder schistosomiasis (bilharzia) is the second most common parasitic infection after malaria, with about 600 million people exposed to infection in Africa, Asia, South America, and the Caribbean [22]. There is a well-established relationship between schistosomiasis and squamous cell carcinoma of the bladder, although a better control of the disease is decreasing the incidence of squamous carcinoma of the bladder in endemic zones such as Egypt [23, 24].

Similarly, invasive squamous cell carcinoma has been linked to the presence of chronic urinary tract infection (UTI) distinct from schistosomiasis. A direct association between BC and UTIs has been observed in several case-control studies, which have reported a two-fold increased risk of BC in patients with recurrent UTIs in some series. However, some of these results may be attributed to recall bias [25].

3.2.6 **Gender**

Although men are more likely to develop BC than women, women present with more advanced disease and have worse survival [26].

It has been suggested that women are more likely to be older than men when diagnosed, with a direct effect on their survival. In addition, delayed diagnosis is more likely in women after haematuria is observed, as the differential diagnosis in women includes diseases that are more prevalent than BC [27].

Differences in the gender prevalence of BC may be due to other factors besides tobacco and chemical

exposure. In a large prospective cohort study, postmenopausal status was associated with an increase in BC risk, even after adjustment for smoking status. This result suggests that the differences in oestrogen and androgen levels between men and women may be responsible for some of the difference in the gender prevalence of BC [28-30]. A large German retrospective multicentre study including 2,483 patients submitted to radical cystectomy showed that cancer-specific mortality was higher in female patients. This difference was more pronounced in earlier time periods. These findings could suggest different tumour biology and potentially unequal access to timely radical cystectomy in earlier periods because of reduced awareness of BC in women [31].

3.2.7 Genetic factors

There is growing evidence that genetic susceptibility factors and family associations may influence the incidence of BC. The relationship between family history of cancer and risk of BC was examined in the Spanish Bladder Cancer Study. It was found that family history of cancer in first-degree relatives was associated with an increased risk of BC; the association being stronger among younger patients. Shared environmental exposure was recognised as a potentially confounding factor [32]. These results support the hypothesis that genetic factors play a role in the aetiology of BC.

Genome-wide association studies (GWAS) of BC identified several susceptibility loci associated with BC risk [33, 34]. Polymorphisms in two carcinogen-metabolizing genes, NATS and GSTM1, have been related to BC risk, and furthermore they have demonstrated, together with UGT1A6, to confer additional risk to exposure of carcinogens such as tobacco smoking [35].

3.2.8 Conclusions and recommendations for epidemiology and risk factors

Conclusions	LE
The incidence of muscle-invasive disease has not changed for 5 years.	
Active and passive tobacco smoking continues to be the main risk factor, while the exposure-related incidence is decreasing.	2a
The increased risk of developing bladder cancer in patients undergoing external-beam radiotherapy (EBRT), brachytherapy, or a combination of EBRT and brachytherapy, must be taken into account during patient follow-up. As bladder cancer requires time to develop, patients treated with radiation at a young age are at the greatest risk and should be followed up closely.	3
The estimated male-to-female ratio for bladder cancer is 3.8:1.0. Women are more likely to be diagnosed with primary muscle-invasive disease than men.	3

Recommendations	GR
The principal preventable risk factor for muscle-invasive bladder cancer is active and passive smoking.	B
Notwithstanding stricter regulations, workers should be informed about the potential carcinogenic effects of a number of recognised substances, duration of exposure, and latency periods. Protective measures should be recommended.	A

GR = grade of recommendation; LE = level of evidence.

3.3 Pathology

3.3.1 Handling of transurethral resection and cystectomy specimens

In transurethral resection (TUR) specimens, the superficial and deep areas of the tumour should be sent to the pathology laboratory separately, in case the outcome will impact on treatment decisions. If random biopsies of the flat mucosa are taken, each biopsy specimen of the flat mucosa should also be sent separately.

In radical cystectomy, bladder fixation must be carried out as soon as possible. The pathologist must open the specimen from the urethra to the bladder dome and fix the specimen in formalin. In some circumstances this procedure can also be performed by the urologist. In a female cystectomy specimen, the length of the urethral segment removed en bloc with the specimen should be checked, preferably by the urological surgeon [36].

Specimen handling should follow the general rules as published by a collaborative group of pathologists and urologists [37, 38]. It must be stressed that it may be very difficult to confirm the presence of a neoplastic lesion using gross examination of the cystectomy specimen after TUR or chemotherapy, so the entire retracted or ulcerated area should be included.

It is compulsory to study the urethra, the ureters, the prostate in men and the radial margins [39]. In urethra-sparing cystectomy, the level of urethral dissection, completeness of the prostate specifically at the apex (in men), and the inclusion of the entire bladder neck and amount of adjacent urethra, uterus and vaginal top (in women) should be documented.

All lymph node specimens should be provided in their totality, in clearly labelled containers. In case of doubt, or adipous differentiation of the lymph node, the entire specimen is to be included.

Lymph nodes should be counted and measured on slides, capsular effraction and percentage of lymph node invasion should be reported as well as vascular embols. In the case of metastatic spread in the perivesical fat without real lymph node structures (capsule, subcapsular sinus), this localisation should nevertheless be considered as N+.

Positive margins in the peripelvic fat tissue (soft tissue margins), should be inked by the pathologist for evaluation. Positive margins have decreased cancer-specific survival (CSS) in cases of pNOM0 urothelial carcinomas [40].

In selected cases, fresh frozen sections may be helpful to determine treatment strategy. A recent study confirmed the reliability of fresh frozen sections of obturator lymph nodes, but similar studies are warranted to confirm these results [41].

3.3.2 **Pathology of muscle-invasive bladder cancer**

In muscle-invasive BC there are usually no cases of PUNLMP and low-grade carcinoma. All cases are high-grade urothelial carcinomas (grade II or grade III). For this reason, no more prognostic information can be provided by grading muscle-invasive BC [42]. However, some morphological subtypes can be important in helping with prognosis and treatment decisions. Currently the following differentiation is used:

1. urothelial carcinoma (more than 90% of all cases);
2. urothelial carcinomas with squamous and/or glandular partial differentiation [43, 44];
3. micropapillary urothelial carcinoma;
4. nested carcinoma [45];
5. some urothelial carcinomas with trophoblastic differentiation;
6. small-cell carcinomas [46];
7. spindle cell carcinomas.

3.3.3 **Recommendations for the assessment of tumour specimens**

<i>Mandatory evaluations</i>
Depth of invasion (categories pT2 vs pT3a, pT3b or pT4).
Margins with special attention paid to the radial margin, prostate, ureter, urethra and peritoneal fat and uterus and vaginal top.
Histological subtype, if it has clinical implications.
Extensive lymph node representation (more than nine).
<i>Optional evaluations</i>
Bladder wall blood vessel invasion.
Pattern of muscle invasion.

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 **Pathological staging**

For staging, TNM 2002/2009 (6th or 7th edition) is recommended (both editions are identical for BC). The pattern of muscular invasion can provide some prognostic information. Most cases show nodular or cordonal growth, but about 44% have an infiltrative pattern. According to some authors [42], the median survival time of a patient with an infiltrative pattern is lower than that for an individual with other pattern types ($p = 0.06$). Blood vessel invasion and lymph node infiltration have an independent prognostic significance [47]. It seems that the pN category is closely related to the number of lymph nodes studied by the pathologist [48]. For this reason, some authors have observed that more than nine lymph nodes have to be investigated to reflect pN0 appropriately [49].

New prognostic markers are under study [50]. Currently, insufficient evidence exists to recommend the standard use of the prognostic marker p53 in high-risk muscle-invasive disease, as it will not yield sufficient

data upon which to base treatment in an individual patient.

4.2 Tumour, node, metastasis classification

The tumour, node, metastasis (TNM) classification of malignant tumours is the method most widely used to classify the extent of cancer spread. A seventh edition was published, effective as of 2010 [51] (Table 4.1). There are no significant modifications in it for BC, compared with the previous edition (2002).

Table 4.1: TNM classification of urinary bladder cancer [51]

T - Primary Tumour	
Tx	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
Tis	Carcinoma <i>in situ</i> : “flat tumour”
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades muscle
T2a	Tumour invades superficial muscle (inner half)
T2b	Tumour invades deep muscle (outer half)
T3	Tumour invades perivesical tissue:
T3a	Microscopically
T3b	Macroscopically (extravesical mass)
T4	Tumour invades any of the following: prostate stroma, seminal vesicles, uterus, vagina, pelvic wall, abdominal wall
T4a	Tumour invades prostate stroma, seminal vesicles, uterus, or vagina
T4b	Tumour invades pelvic wall or abdominal wall
N - Regional Lymph Nodes	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph-node metastasis
N1	Metastasis in a single lymph node in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N2	Metastasis in multiple lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N3	Metastasis in common iliac lymph node(s)
M - Distant Metastasis	
M0	No distant metastasis
M1	Distant metastasis

5. DIAGNOSTIC EVALUATION

5.1 Primary diagnosis

5.1.1 Symptoms

Painless haematuria is the most common presenting complaint. Others include urgency, dysuria, increased frequency, and in more advanced tumours, pelvic pain and symptoms related to urinary tract obstruction.

5.1.2 Physical examination

Physical examination should include rectal and vaginal bimanual palpation. A palpable pelvic mass can be found in patients with locally advanced tumours. In addition, bimanual examination under anaesthesia should be carried out before and after TURB, to assess whether there is a palpable mass or if the tumour is fixed to the pelvic wall [52, 53]. However, considering the discrepancy between bimanual examination and pT stage after cystectomy (11% clinical overstaging and 31% clinical understaging), some caution is suggested with the interpretation of bimanual examination [54].

5.1.3 Bladder imaging

Patients with a bladder mass identified by any diagnostic imaging technique should undergo cystoscopy, biopsy and/or resection for histopathological diagnosis and staging.

5.1.4 **Urinary cytology and urinary markers**

Examination of voided urine or bladder washings for exfoliated cancer cells has high sensitivity in high-grade tumours (LE: 3) and is a useful indicator in cases of high-grade malignancy or CIS.

Positive urinary cytology may originate from a urothelial tumour located anywhere in the urinary tract. Evaluation of cytology specimens can be hampered by low cellular yield, UTIs, stones or intravesical instillations, but for experienced readers, specificity exceeds 90% [55, 56] (LE: 2b). However, negative cytology does not exclude tumour. There is no known urinary marker specific for the diagnosis of invasive BC [57].

5.1.5 **Cystoscopy**

Ultimately, the diagnosis of BC is made by cystoscopy and histological evaluation of resected tissue. In general, cystoscopy is initially performed in the office using a flexible instrument. If a bladder tumour has been visualised unequivocally in earlier imaging studies, such as computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound (US), diagnostic cystoscopy may be omitted and the patient can proceed directly to TURB for histological diagnosis. Currently, there is no evidence for the role of photodynamic diagnosis (PDD) in the diagnosis of invasive BC.

A careful description of the cystoscopic findings is necessary. This should include documentation of the site, size, number, and appearance (papillary or solid) of the tumours, as well as a description of mucosal abnormalities. Use of a bladder diagram is recommended.

The use of photodynamic diagnosis could be considered, especially if a T1 high-grade tumour is present, to find associated CIS. The additional presence of CIS may lead to a modified treatment plan (see Section 7.1). Photodynamic diagnosis is highly sensitive for the detection of CIS, but in experienced hands, the rate of false-positive results may be similar to that with regular white-light cystoscopy [58].

5.1.6 **Transurethral resection of invasive bladder tumours**

The goal of TURB is to enable histopathological diagnosis and staging, which requires the inclusion of bladder muscle in the resection biopsies.

The strategy of resection depends on the size of the lesion. Small tumours (< 1 cm in diameter) can be resected *en bloc*, where the specimen contains the complete tumour plus a part of the underlying bladder wall including muscle. Larger tumours need to be resected separately in parts, which include the exophytic part of the tumour, the underlying bladder wall with the detrusor muscle, and the edges of the resection area. At least the deeper part of the resection specimen must be referred to the pathologist in a separate labelled container to enable him/her to make a correct diagnosis. In cases in which radiotherapy is considered and CIS is to be excluded, photodynamic diagnosis can be used [59].

The involvement of the prostatic urethra and ducts in men with bladder tumours has been reported. The exact risk is not known, but it seems to be higher if the tumour is located on the trigone or bladder neck, in the presence of bladder CIS, and in multiple tumours [60, 61] (LE: 3). Involvement of the prostatic urethra can be determined either at the time of primary TURB or by frozen section during the cystoprostatectomy procedure. A frozen section has a higher negative predictive value and is more accurate [62-64].

5.1.7 **Second resection**

In the case of high-grade non-muscle-infiltrative tumour, residual disease is observed in 33-53% of patients [65-71]. In order to reduce the risk of understaging [66, 67], a second TURB resection is often required to determine the future treatment strategy.

Diagnosis of urethral tumour before cystectomy or positive urethral frozen section leads to urethrectomy and therefore excludes neobladder reconstruction. If indicated, in males, urethral frozen section has to be performed on the cysto-prostatectomy specimen just below the verumontanum bladder neck and on the inferior limits of the bladder neck for females.

5.1.8 **Concomitant prostate cancer**

Prostate cancer is found in 25-46% of patients undergoing cystectomy for BC [72, 73]. The impact on survival is unknown, however, the impact on surgical treatment is limited.

5.1.9 **Specific recommendations for the primary assessment of presumably invasive bladder tumours**

(For general information on the assessment of bladder tumours, see EAU Guidelines on Non-muscle-invasive Bladder cancer [2]).

Conclusion	LE
Currently, treatment decisions cannot be based on molecular markers.	3

Recommendations	GR
Cystoscopy should describe all macroscopic features of the tumour (site, size, number and appearance) and mucosal abnormalities. A bladder diagram is recommended.	C
Biopsy of the prostatic urethra is recommended for cases of bladder neck tumour, when bladder CIS is present or suspected, when there is positive cytology without evidence of tumour in the bladder, or when abnormalities of the prostatic urethra are visible.	
If biopsy is not performed during the initial procedure, it should be completed at the time of the second resection.	C
In women undergoing subsequent orthotopic neobladder construction, procedural information is required (including histological evaluation) of the bladder neck and urethral margin, either prior to or at the time of cystoscopy.	C
The pathological report should specify the grade, depth of tumour invasion, and whether the lamina propria and muscle tissue are present in the specimen.	C

CIC = carcinoma in situ; GR = grade of recommendation; LE = level of evidence.

5.2 Imaging for staging of MIBC

The treatment and prognosis of MIBC is determined by tumour stage and grade [74]. In clinical practice, CT and MRI are the imaging techniques used. The purpose of using imaging for staging MIBC is to determine prognosis and provide information to assist treatment selection. Tumour staging must be accurate to ensure that the correct choice of treatment is made. Imaging parameters required for staging MIBC are:

- extent of local tumour invasion;
- tumour spread to lymph nodes;
- tumour spread to the upper urinary tract (UUT) and other distant organs (e.g., liver, lungs, bones, peritoneum, pleura, and adrenal glands).

5.2.1 Local staging of MIBC

Both CT and MRI may be used for assessment of local invasion, but they are unable to accurately diagnose microscopic invasion of perivesical fat (T2 versus T3a) [75]. The principal aim of CT and MRI is therefore to detect T3b disease or higher.

5.2.1.1 MRI for local staging of invasive bladder cancer

Magnetic resonance imaging has superior soft tissue contrast resolution compared with CT, but poorer spatial resolution. In studies performed before the availability of multidetector CT, MRI was reported as more accurate in local assessment. The accuracy of MRI for primary tumour staging varies from 73% to 96% (mean 85%). These values were 10-33% (mean 19%) higher than those obtained with CT [76]. Dynamic contrast-enhanced (DCE) MRI may help to differentiate bladder tumour from surrounding tissues or post-biopsy reaction, because enhancement of the tumour occurs earlier than that of the normal bladder wall, due to neovascularisation [77-79].

In 2006, a link was established between the use of gadolinium-based contrast agents and nephrogenic systemic fibrosis (NSF), which may result in fatal or severely debilitating systemic fibrosis. Patients with impaired renal function are at risk of developing NSF and the non-ionic linear gadolinium-based contrast agents should be avoided (gadodiamide, gadopentetate dimeglumine and gadoversetamide). A stable macrocyclic contrast agent should be used (gadobutrol, gadoterate meglumine or gadoteridol). Contrast-enhanced CT using iodinated contrast media should be considered as an alternative [80] (LE: 4).

5.2.1.2 CT imaging for local staging of MIBC

The advantages of CT include high spatial resolution, shorter acquisition time, wider coverage in a single breath hold, and lower susceptibility to variable patient factors. Computed tomography is unable to differentiate between stages from Ta to T3a tumours, but it is useful for detecting invasion into the perivesical fat (T3b) and adjacent organs. The accuracy of CT in determining extravesical tumour extension varies from 55% to 92% [81] and increases with more advanced disease [82].

5.2.2 Imaging of lymph nodes in MIBC

Assessment of lymph node metastases based solely on size is limited by the inability of both CT and MRI to identify metastases in normal-sized or minimally enlarged nodes. The sensitivity for detection of lymph node metastases is low (48-87%). Specificity is also low because nodal enlargement may be due to benign disease. Overall, CT and MRI show similar results in the detection of lymph node metastases in a variety of primary pelvic tumours [83-88]. Pelvic nodes > 8 mm and abdominal nodes > 10 mm in maximum short-axis diameter, detected by CT or MRI, should be regarded as pathologically enlarged [89, 90].

Currently, there is no evidence supporting the routine use of positron emission tomography (PET) in the nodal staging of BC, although the method has been evaluated with varying results in small prospective trials [91-94].

5.2.3 **Upper urinary tract urothelial carcinoma**

Excretory-phase CT urography is the imaging technique with the highest diagnostic accuracy for upper urinary tract urothelial carcinoma (UTUC) and has replaced conventional intravenous urography and US as the first-line imaging test for investigating high-risk patients [95]. The sensitivity of CT urography for UTUC is reported to range from 0.67 to 1.0 and specificity from 0.93 to 0.99, depending on the technique used [96-103]. Attention to technique is therefore important for optimum results.

For UTUC detected by CT urography, a biopsy for histopathological confirmation of diagnosis is recommended to eliminate false-positive results and to provide information regarding the grade of the tumour to aid in the choice of treatment [97, 98, 104-106]. The biopsy is usually performed endoscopically.

5.2.4 **Distant metastases at sites other than lymph nodes**

Prior to any curative treatment, it is essential to evaluate the presence of distant metastases. Computed tomography and MRI are the diagnostic techniques of choice to detect lung [107] and liver metastases [108], respectively. Bone and brain metastases are rare at the time of presentation of invasive BC. A bone scan and additional brain imaging are therefore not routinely indicated unless the patient has specific symptoms or signs to suggest bone or brain metastases [109, 110]. Magnetic resonance imaging is more sensitive and specific for diagnosing bone metastases than bone scintigraphy [111, 112] (LE: 2b).

5.2.5 **Future developments**

Evidence is accruing in the literature suggesting that fluorodeoxyglucose (FDG)-PET/CT might have potential clinical use for staging metastatic BC [113, 114], but there is no consensus as yet. The results of further trials are awaited before a recommendation can be made. Recently, the first study was published showing the superior feasibility of diffusion-weighted imaging (DWI) over T2-weighted and DCE MRI for assessing the therapeutic response to induction chemotherapy against MIBC [115]. The high specificity of DWI indicates that it is useful for accurate prediction of a complete histopathological response, allowing better patient selection for bladder-sparing protocols. Results from prospective studies are awaited.

5.2.6 **Conclusion and recommendations for staging in MIBC**

Conclusion	LE
Imaging as part of staging in MIBC provides information about prognosis and assists in selection of the most appropriate treatment.	2b
There are currently insufficient data on the use of DWI and FDG-PET/CT in MIBC to allow a recommendation to be made.	

Recommendations	GR
In patients with confirmed MIBC, CT of the chest, abdomen and pelvis is the optimal form of staging, including excretory-phase CT urography for complete examination of the upper urinary tract.	B
Excretory-phase CT urography is preferred to MR urography for the diagnosis of UTUC in terms of greater diagnostic accuracy, less cost, and greater patient acceptability. MR urography is used when CT urography is contraindicated for reasons related to contrast administration or radiation dose.	C
Endoscopically-guided biopsy is recommended for histopathological confirmation of preoperative diagnosis of UTUC.	C
CT or MRI is recommended for staging locally advanced or metastatic disease in patients in whom radical treatment is being considered.	B
CT and MRI are generally equivalent for diagnosing local disease and distant metastases in the abdomen. CT is preferred for diagnosis of pulmonary metastases.	C

CT = computed tomography; DWI = diffusion-weighted imaging; FDG-PET/CT = fluorodeoxyglucose-positron emission tomography; GR = grade of recommendation; LE = level of evidence; MIBC = muscle-invasive bladder cancer; MRI = magnetic resonance imaging; UTUC = upper urinary tract urothelial carcinoma.

6. PROGNOSIS

6.1 Introduction

The treatment and prognosis for MIBC is determined by tumour stage and grade [74]. In clinical practice, CT and MRI are the imaging techniques used.

6.2 MIBC and comorbidity

Complications related to radical cystectomy may be directly related to pre-existing comorbidity as well as the surgical procedure, bowel anastomosis, or urinary diversion. A significant body of literature has evaluated the usefulness of age as a prognostic factor for radical cystectomy [116-118]. Advanced age has been identified as a risk factor for complications in the case of radical cystectomy, although chronological age is less important than biological age. Other risk factors for morbidity include prior abdominal surgery, extravesical disease, and prior radiotherapy [119], while an increased body mass index is associated with a higher rate of wound dehiscence and hernia [120].

6.2.1 Evaluation of comorbidity

Rochon et al. have shown that evaluation of comorbidity provides a better indicator of life expectancy in MIBC than patient age [121]. The evaluation helps to identify the medical conditions likely to interfere with, or have an impact on, treatment and the evolution and prognosis of MIBC [122].

The value of assessing overall health before recommending and proceeding with surgery was emphasised by Zietman et al., has demonstrated an association between comorbidity and adverse pathological and survival outcome following radical cystectomy [123]. Similar results were found for the impact of comorbidity on cancer-specific and other-cause mortality in a population-based competing risk analysis of > 11,260 patients from the SEER registries. Age carried the highest risk for other-cause mortality but not for increased cancer-specific death, while the stage of locally advanced tumour was the strongest predictor for decreased CSS [124]. Stratifying elderly patients according to their risk-benefit profile using a multidisciplinary approach will help to select patients most likely to benefit from radical surgery and to optimise treatment outcomes [125]. Unfortunately, most series evaluating radical cystectomy do not include indices of comorbidity in the patient evaluation.

6.2.2 Comorbidity scales, anaesthetic risk classification and geriatric assessment

A range of comorbidity scales has been developed [126]; six of which have been validated [127-132] (LE: 3).

The Charlson Comorbidity Index (CCI) ranges from 0 to 30 according to the importance of comorbidity described at four levels and is calculated by healthcare practitioners from the patients' medical records. The score has been widely studied in patients with BC and found to be an independent prognostic factor for perioperative mortality [133, 134], overall mortality [135], and cancer-specific mortality [136-139]. Only the age-adjusted version of the CCI was correlated with both cancer-specific and other-cause mortality [140].

The age-adjusted CCI (Table 6.1) is the most widely used comorbidity index in cancer for estimating long-term survival and is easily calculated [141].

Table 6.1: Calculation of the Charlson Comorbidity Index

Number of points	Conditions
1 point	50-60 years Myocardial infarction Heart failure Peripheral vascular insufficiency Cerebrovascular disease Dementia Chronic lung disease Connective tissue disease Ulcer disease Mild liver disease Diabetes
2 points	61-70 years Hemiplegia Moderate to severe kidney disease Diabetes with organ damage Tumours of all origins

3 points	71-80 years Moderate to severe liver disease
4 points	81-90 years
5 points	> 90 years
6 points	Metastatic solid tumours AIDS

Interpretation

1. Calculate Charlson Score or Index = i
 - a. Add comorbidity score to age score
 - b. Total denoted as 'i' in the Charlson Probability calculation (see below). i = sum of comorbidity score to age score
2. Calculate Charlson Probability (10-year mortality)
 - a. Calculate $Y = 10^{(i \times 0.9)}$
 - b. Calculate $Z = 0.983^Y$ (where Z is the 10-year survival)

Health assessment of oncology patients must be supplemented by measuring their activity level. Extermann et al. have shown that there is no correlation between morbidity and competitive activity level [142]. Eastern Cooperative Oncology Group (ECOG) PS scores and Karnofsky index have been validated to measure patient activity [143] (LE: 3). PS is correlated with patient OS after radical cystectomy [138, 144] and palliative chemotherapy [145-147].

The ASA score has been validated to assess the risk of postoperative complications prior to surgery. In the BC setting, ASA scores ≥ 3 are associated with major complications [148, 149], particularly those related to the type of urinary diversion (Table 6.2) [150]. However, the ASA score is not a comorbidity scale and should not be used as such.

Table 6.2: ASA score [151]

ASA	
1	No organic pathology, or patients in whom the pathological process is localised and does not cause any systemic disturbance or abnormality.
2	A moderate but definite systemic disturbance caused either by the condition that is to be treated or surgical intervention, or which is caused by other existing pathological processes.
3	Severe systemic disturbance from any cause or causes. It is not possible to state an absolute measure of severity, as this is a matter of clinical judgment.
4	Extreme systemic disorders that have already become an imminent threat to life, regardless of the type of treatment. Because of their duration or nature, there has already been damage to the organism that is irreversible.
5	Moribund patients not expected to survive 24 h, with or without surgery.

According to a consensus conference of the National Institutes of Health, the aim of the Standardized Geriatric Assessment (SGA) is to discover, describe and explain the many problems of elderly people, to catalogue their resources and strengths, to assess individual service needs, and to develop a coordinated plan of care. The SGA can be carried out by means of several protocols. These protocols differ in the completeness of diagnostic research. The protocol is the most complete Comprehensive Geriatric Assessment (CGA) [152]. The CGA is suited to the care of cancer patients [153]. In BC, the CGA has been used to adapt gemcitabine chemotherapy in previously untreated elderly patients with advanced bladder carcinoma [154].

6.2.3 Conclusions and recommendations for comorbidity scales

Conclusions	LE
Chronological age is of limited relevance	3
A comorbidity score developed in particular for assessment of patients diagnosed with bladder cancer would be helpful.	3

Recommendations	GR
The decision regarding bladder-sparing or radical cystectomy in elderly/geriatric patients with invasive bladder cancer should be based on tumour stage and comorbidity best quantified by a validated score, such as the Charlson Comorbidity Index.	B
The ASA score does not address comorbidity and should not be used in this setting.	B

ASA = American Society of Anesthesiologists; GR = grade of recommendation; LE = level of evidence.

7. DISEASE MANAGEMENT

7.1 Treatment failure of non-muscle-invasive bladder cancer

7.1.1 High-risk non-muscle-invasive urothelial carcinoma

The recurrence and progression rates of non-muscle-invasive BC (NMIBC) is strongly associated with several factors as described in the EORTC risk calculator [155]. According to this calculator, the risk of progression after 5 years ranges from 6 to 45% for high-risk tumours. However, in a prospective, multicentre trial, the progression rate was significantly lower than previously reported, even when the presence of concomitant CIS was considered. This was probably due to the combination of a second resection, prior to inclusion in the trial and maintenance treatment as part of the protocol [156]. Meta-analyses have demonstrated that Bacillus Calmette-Guérin (BCG) therapy prevents the risk of tumour recurrence [157, 158].

Two other meta-analyses have shown that BCG therapy decreases the risk of tumour progression [159, 160] but so far, no significant overall- or disease-specific survival advantages have been shown, as compared to no intravesical therapy [159-161].

As also reported in the EAU NMIBC guidelines, there are reasons to consider cystectomy in selected patients with NMIBC [2].

There is a risk of an understaging error in Ta, T1 tumours of 35-62% presented in large cystectomy series. This seems due to the presence of persisting or recurrent tumours due to the lack of a second TURB or re-TURB and the absence of neoadjuvant therapy [162-164]. Second TURB identifies 24-49% of T2 tumours that have been diagnosed initially as non-muscle-invasive tumours [67, 165]. Progression to MIBC significantly decreases cancer-specific survival (CSS). In a review of 19 trials including 3,088 patients, CSS after progression from NMIBC to MIBC was 35%, which is significantly worse compared to patients with MIBC without a history of NMIBC. This underlines the need to recommend early radical treatment, such as f.i. radical cystectomy, in the case of intravesical therapy failure [2, 166, 167].

According to the EAU NMIBC Guidelines, it is reasonable to propose immediate radical cystectomy to those patients with non-muscle-invasive tumour who are at highest risk of progression [166]. These are:

- T1 tumour
- G3** (high-grade) tumour
- CIS
- Multiple and recurrent and large (> 3 cm) Ta G1G2 tumours (all conditions must be presented in this point)*.

*low grade is a mixture of G1 and G2.

** high grade is a mixture of some G2 and all G3.

Although the percentage of patients with primary Ta, T1 tumours and the indication for cystectomy in Ta, T1 tumours is not specified in large cystectomy series, the 10-year recurrence-free survival rate is ~80% and similar to that with TURB and BCG maintenance therapy [2, 163, 168, 169] (LE: 3).

Radical cystectomy is also strongly recommended in patients with BCG-refractory tumours, defined in the NMIBC guideline as:

- whenever muscle-invasive tumour is detected during follow-up;
- if high-grade, non-muscle-invasive papillary tumour is present at 3 months;
- if CIS (without concomitant papillary tumour) is present at both 3 and 6 months;
- If high-grade tumour appears during BCG therapy;
- high-grade recurrence after BCG (Recurrence of high-grade/grade 3 [WHO 2004/1973] tumour after completion of BCG maintenance, despite an initial response).

Patients with disease recurrence within 2 years of initial TURB plus BCG therapy have a better outcome than patients who already have muscle-invasive disease, indicating that cystectomy should be performed at first recurrence, even in non-muscle-invasive disease [167] (LE: 3; GR: C).

There are now several bladder-preservation strategies available that can be categorised as immunotherapy, chemotherapy, device-assisted therapy, and combination therapy [170]. However, experience is limited and treatments other than radical cystectomy must be considered oncologically inferior at the present time [171-173].

7.1.2 **Recommendations for treatment failure of non-muscle-invasive bladder cancer**

Recommendations	GR
In all T1 tumours at high risk of progression (i.e., high grade, multifocality, CIS, and tumour size, as outlined in the EAU guidelines for non-muscle-invasive bladder cancer [2]), immediate radical treatment is an option.	C
In all T1 patients failing intravesical therapy, radical treatment should be offered.	B

CIS = carcinoma in situ; GR = grade of recommendation.

7.2 **Neoadjuvant chemotherapy**

7.2.1 **Introduction**

The standard treatment for patients with muscle-invasive BC is radical cystectomy. However, this gold standard only provides 5-year survival in about 50% [164, 174-177]. To improve these unsatisfactory results, neoadjuvant chemotherapy (NAC) has been used since the 1980s [178, 179].

There are many advantages and disadvantages of administering chemotherapy before planned definitive surgery to patients with operable muscle-invasive urothelial carcinoma of the bladder and cN0M0:

- Chemotherapy is delivered at the earliest time-point, when the burden of micrometastatic disease is expected to be low.
- Potential reflection of in vivo chemosensitivity.
- Tolerability of chemotherapy and patient compliance are expected to be better pre-cystectomy.
- Patients might respond to NAC and reveal a favourable pathological status, determined mainly by achieving pT0, pN0 and negative surgical margins.
- Delayed cystectomy might compromise the outcome in patients not sensitive to chemotherapy [180, 181], although published studies on the negative effect of delayed cystectomy only entail series of chemo-naïve patients. There are no trials indicating that delayed surgery, due to NAC, has a negative impact on survival.
- Neoadjuvant chemotherapy does not seem to affect the outcome of surgical morbidity. In one randomised trial the same distribution of grade 3-4 postoperative complications was seen in both trial arms [182].

In the combined Nordic trials (n = 620), NAC did not have any major adverse effect on the percentage of performable cystectomies. The cystectomy frequency was 86% in the experimental arm and 87% in the control arm, 71% received all three chemotherapy cycles [183].

- Clinical staging using bimanual palpation, CT or MRI may often result in over- and understaging and have a staging accuracy of only 70% [184, 185]. Overtreatment is a possible negative consequence.
- NAC should only be used in patients eligible for cisplatin combination chemotherapy; other combinations (or monotherapies) are inferior in metastatic BC and have not been tested adequately in the neoadjuvant setting [182, 186-198].

7.2.2 **The role of imaging and biomarkers to identify responders**

In small published series entailing imaging, attempts to identify the responders among patients undergoing NAC, suggested that response after two cycles of treatment is related to outcome. To date, no firm conclusions can be made [199, 200]. The definition of stable disease after two cycles of NAC is still undefined. To identify progression during NAC, imaging is being used in many centres, notwithstanding the lack of supporting evidence.

For responders to NAC, especially in those with a complete response (pT0 N0), treatment has a major positive impact on overall survival (OS) [201]. The overtreatment of non-responders and patients in the non-target population (i.e. patients without micrometastatic disease) are major drawbacks of NAC. Preoperative

identification of responders utilizing tumour molecular profiling in TURB specimens might guide the use of NAC [202, 203] (see Section 7.8.11 - Biomarkers). In addition, imaging methods for the early identification of responders during treatment have been explored. So far, neither PET, CT, nor conventional MRI or DCE MRI can accurately predict response [199, 200, 204, 205].

7.2.3 Summary of available data

Several randomised phase III trials have addressed the question of NAC improving survival, with conflicting results [182, 186-195, 206-211]. The main differences in trial design were the type of chemotherapy (i.e. single-agent cisplatin or combination chemotherapy) and the number of cycles planned. From the statistical point of view, the studies differed in size, patient characteristics (e.g. clinical T-stages included) and the type of definitive treatment allowed (cystectomy and/or radiotherapy). Patients had to be fit for cisplatin. As a result of the lack of clarity, even though a considerable number of randomised trials had been performed, three meta-analyses were undertaken to answer the important question of whether NAC prolongs survival or not [196-198].

In the most recent meta-analysis, published in 2005 [198], with updated patient data from 11 randomised trials (3,005 patients), a significant survival benefit was shown in favour of NAC. The results of this analysis confirmed the previously published data and showed a 5% absolute improvement in survival at 5 years. The Nordic combined trial showed an absolute benefit of 8% survival at 5 years and 11% in the clinical T3 subgroup, translating into nine patients needed to treat [183]. Only cisplatin combination chemotherapy with at least one additional chemotherapeutic agent resulted in a meaningful therapeutic benefit [196, 198]; the regimens tested were MVA(E)C, CMV, CM, cisplatin/adriamycin, cisplatin/5-fluorouracil (5-FU), and CarboMV. More modern chemotherapy regimens like gemcitabine/cisplatin have shown similar pT0/pT1 rates as MVAC in the most recent retrospective series and pooled data analysis, but have not been used in randomised controlled trials [212-215].

The updated analysis of the largest randomised phase III trial [186] with a median follow-up of 8 years confirmed previous results and provided some additional interesting findings:

- 16% reduction in mortality risk;
- Improvement in 10-year survival from 30% to 36% with neoadjuvant CMV;
- Benefit with regard to distant metastases; No benefit for locoregional control and locoregional disease-free survival, with the addition of neoadjuvant CMV independent of the definitive treatment.

The presence of micrometastases is postulated to be lower in smaller tumours (T2) compared to more extensive tumours (T3b-T4b). T4 stage tumours are prone to a higher degree of clinical understaging because macrometastatic nodal deposits are detected more often in post-cystectomy specimens of these extensive tumours [183]. Further data support the use of NAC in the T2b-T3b tumour subgroup (former classification T3), which has shown to provide a modest but substantial improvement in long-term survival and significant downstaging [201].

7.2.4 Conclusions and recommendations for neoadjuvant chemotherapy

Conclusions	LE
Neoadjuvant chemotherapy has its limitations regarding patient selection, current development of surgical techniques, and current chemotherapy combinations.	3
Neoadjuvant cisplatin-containing combination chemotherapy improves OS (5-8% at 5 years).	1a
Neoadjuvant treatment of responders, and especially patients who show complete response (pT0 N0) has a major impact on OS.	2
Currently, no tools are available to select patients who have a higher probability of benefitting from neoadjuvant chemotherapy. In the future, genetic markers, in a personalised medicine setting, might facilitate the selection of patients for neoadjuvant chemotherapy and differentiate responders from non-responders.	

Recommendations	GR
Neoadjuvant chemotherapy is recommended for T2-T4a, cN0M0 bladder cancer and should always be cisplatin-based combination therapy.	A
Neoadjuvant chemotherapy is not recommended in patients who are ineligible for cisplatin-based combination chemotherapy.	A

GR = grade of recommendation; LE = level of evidence; OS = overall survival.

7.3 Pre- and postoperative radiotherapy in muscle-invasive bladder cancer

There is very limited and only older data on adjuvant radiotherapy after radical cystectomy. However, advances in targeting, reducing damage to surrounding tissue, may yield better results in the future [216]. A recent RCT in 100 patients, comparing pre-operative versus post-operative radiotherapy and radical cystectomy, showed comparable OS, DFS and complication rates [217]. Approximately half of these patients had UC, while the other half had squamous cell carcinoma.

7.3.1 Pre-operative radiotherapy

7.3.1.1 Retrospective studies

Several old and retrospective studies reporting on pre-operative radiotherapy at doses over 40 Gy, followed after 4-6 weeks by cystectomy, showed down-staging, improved local control, especially in T3b tumours, and an improved survival, especially in complete responders to radiotherapy (references available upon request). However, these results cannot be used as a basis for modern Guideline advice due to major study limitations, including concomitant chemotherapy and differences in surgery and radiotherapy. This conclusion was supported by a 2003 systematic review [218]. A more recent retrospective study compared the long-term outcome of pre-operative versus no pre-operative radiotherapy in clinical T1-3 tumours [219]. Down-staging to T0 after cystectomy occurred in 7% (7/97) without radiotherapy versus 57% (51/90) with radiotherapy. In cT3 tumours, these results were 0% (0/16) versus 59% (19/34), respectively. Down-staging resulted in a longer PFS.

7.3.1.2 Randomised studies

Six randomised studies were published investigating pre-operative radiotherapy, although again from several decades ago. In the largest trial, pre-operative radiotherapy at a dose of 45 Gy was used in patients with muscle-invasive tumours [220]. There was a significant increase in pCR (9% to 34%) in favour of pre-operative radiotherapy, which was also a prognostic factor for better survival. The OS data was difficult to interpret because chemotherapy was used in a subset of patients and > 50% of patients (241/475) did not receive the planned treatment and were excluded for the final analyses. Two smaller studies using a dose of 20 Gy did not show a survival advantage or only a small advantage in \geq T3 tumours [221, 222]. Two other small trials confirmed down-staging after pre-operative radiotherapy [223, 224].

A meta-analysis of the above five randomised trials showed an odds ratio for the difference in 5-year survival of 0.71 (95% CI: 0.48-1.06) in favour of pre-operative radiotherapy [225]. However, the meta-analysis was potentially biased by the patients in the largest trial who were not given the planned treatment. When the largest trial was excluded, the odds ratio was 0.94 (95% CI: 0.57-1.55, which is not significant).

7.3.2 Conclusions and recommendations for pre- and postoperative radiotherapy

Conclusions	LE
No data exist to support that pre-operative radiotherapy for operable MIBC increases survival.	2a
Pre-operative radiotherapy for operable MIBC, using a dose of 45-50 Gy in fractions of 1.8-2 Gy, results in down-staging after 4-6 weeks.	2
Limited high-quality evidence supports the use of pre-operative radiotherapy to decrease local recurrence of MIBC after radical cystectomy.	3

Recommendations	GR
Pre-operative radiotherapy is not recommended to improve survival.	A
Pre-operative radiotherapy for operable MIBC can result in tumour down-staging after 4-6 weeks.	C

GR = grade of recommendation; LE = level of evidence; MIBC = muscle-invasive bladder cancer.

7.4 Radical surgery and urinary diversion

7.4.1 Removal of the tumour-bearing bladder

7.4.1.1 Introduction

Radical cystectomy is the standard treatment for localised MIBC in most Western countries [164, 226]. Recent interest in patients' quality of life (QoL) has promoted the trend toward bladder-preserving treatment modalities, such as radio- and/or chemotherapy (see Sections 7.2 and 7.6). Performance status (PS) and age influence the choice of primary therapy, as well as the type of urinary diversion, with cystectomy being reserved for younger patients without concomitant disease and with a better PS. The value of assessing overall health before recommending and proceeding with surgery was emphasised in a multivariate analysis [136]. The analysis found an association between comorbidity and adverse pathological and survival outcome following radical cystectomy [136]. Performance status and comorbidity have a different impact on treatment outcomes and must be evaluated independently [142].

Controversy remains regarding age, radical cystectomy and the type of urinary diversion. Cystectomy is associated with the greatest risk reduction in disease-related and non-disease-related death in patients aged > 80 years [136]. The largest, retrospective, single-institution study on cystectomy to date found that patients aged > 80 years had increased postoperative morbidity, but not increased mortality. Although some patients successfully underwent a neobladder procedure, most patients were treated with an ileal conduit diversion [227].

It is particularly important to evaluate the function and QoL of elderly patients using a standardised geriatric assessment, as well as carrying out a standard medical evaluation (see Section 6.2) [228].

7.4.2 Timing and delay of cystectomy

Nielsen et al. reported that a delay of radical cystectomy > 3 months in three American centres, was not associated with a worse clinical outcome [229]. Ayres et al. investigated whether a delay > 3 months would have the same effect in England [230]. Initially they found, in agreement with Nielsen et al, that cystectomy within 90 days of diagnosis had no effect on OS for MIBC (n = 955). However, analysis of T2 tumours showed a statistically significant survival benefit if patients had surgery within 90 days of diagnosis (n = 543; HR 1.40, 95% CI 1.10-1.79). A population-based study from the US SEER-database analysed patients who underwent a cystectomy between 1992 and 2001, also concluded that a delay of more than 12 weeks has a negative impact on outcome and should be avoided [231].

7.4.2.1 Indications

Traditionally, radical cystectomy was recommended for patients with MIBC T2-T4a, N0-Nx, M0 [226]. Other indications include high-risk and recurrent superficial tumours, BCG-resistant Tis, T1G3 (see Section 7.1), as well as extensive papillary disease that cannot be controlled with TURB and intravesical therapy alone. Salvage cystectomy is indicated in non-responders to conservative therapy, recurrence after bladder-sparing treatment, and non-urothelial carcinoma (these tumours respond poorly to chemo- and radiotherapy). It is also used as a purely palliative intervention, including in fistula formation, for pain or recurrent visible haematuria (macrohaematuria) (see Section 7.5.1 - Palliative cystectomy).

When there are positive lymph nodes, in the case of N1 involvement (metastasis in a single node in the true pelvis) orthotopic neobladder can still be considered, but not in N2 or N3 tumours [232].

7.4.3 Radical cystectomy: technique and extent

In men, standard radical cystectomy includes removal of the bladder, prostate, seminal vesicles, distal ureters, and regional lymph nodes. In women, standard radical cystectomy includes removal of the bladder, entire urethra and adjacent vagina, uterus, distal ureters, and regional lymph nodes [233]. Controversies in evaluating the clinical significance of lymphadenectomy are related to two main aspects of nodal dissection: therapeutic procedure and/or staging instrument.

Two important autopsy investigations for radical cystectomy have been performed so far. The first investigation showed that in 215 patients with MIBC and nodal dissemination, the frequency of metastasis was 92% in regional (perivesical or pelvic), 72% in retroperitoneal, and 35% in abdominal lymph nodes. There was also a significant correlation between nodal metastases and concomitant distant metastases ($P < 0.0001$). Approximately 47% of the patients had both nodal metastases and distant dissemination and only 12% of the patients had nodal dissemination as the sole metastatic manifestation [234]. The second autopsy investigation focussed on the nodal yield when super-extended pelvic lymph node dissection (LND) was performed. Substantial inter-individual differences were found with counts ranging from 10 to 53 nodes [235]. These findings demonstrate the limited utility of node count as a surrogate for extent of dissection.

Regional lymph nodes have been shown to consist of all pelvic lymph nodes below the bifurcation of the aorta [236-240]. Mapping studies have also found that skip lesions at locations above the bifurcation of the aorta, without more distally located lymph node metastases, are rare [240, 241].

The extent of LND has not been established to date. Standard lymphadenectomy in bladder cancer patients involves removal of nodal tissue cranially up to the common iliac bifurcation, with the ureter being the medial border, and including the internal iliac, presacral, obturator fossa and external iliac nodes [242]. Extended lymphadenectomy includes all lymph nodes in the region of the aortic bifurcation, and presacral and common iliac vessels medial to the crossing ureters. The lateral borders are the genitofemoral nerves, caudally the circumflex iliac vein, the lacunar ligament and the lymph node of Cloquet, as well as the area described for standard lymphadenectomy [242-246]. A super-extended lymphadenectomy extends cranially to the level of the inferior mesenteric artery [247, 248].

In order to assess how and if cancer outcome is influenced by the extent of lymphadenectomy in patients with clinical N0M0 MIBC, a systematic review of the literature was undertaken [5]. Out of 1,692 abstracts retrieved and assessed, 19 studies fulfilled the review criteria and were included [242-246, 248-261]. All five studies comparing LND versus no LND reported a better oncological outcome for the former group. Seven out of 12 studies comparing (super-)extended with limited or standard LND reported a beneficial outcome for (super-)extended in at least a subset of patients. No difference in outcome was reported between extended and super-extended LND in the two high-volume-centre studies identified [248, 259].

Two other reviews reported that more limited pelvic LND was associated with suboptimal staging as well as poorer outcome compared with standard or extended LND [262, 263]. However, all of these identified studies suffered from significant methodological limitations and were prone to bias, thereby compromising the quality and reliability of the evidence. Further data from on-going randomised trials on the therapeutic impact of the extent of lymphadenectomy are awaited.

It has been suggested that progression-free survival as well as OS might be correlated with the number of lymph nodes removed during surgery, although there are no data from randomised controlled trials on the minimum number of lymph nodes that should be removed. Nevertheless, survival rates increase with the number of dissected lymph nodes [264]. Removal of at least 10 lymph nodes has been postulated as sufficient for evaluation of lymph node status, as well as being beneficial for OS in retrospective studies [265-267]. In conclusion, extended LND might have a therapeutic benefit compared to less-extensive LND, but due to bias, no firm conclusions can be drawn [5].

7.4.3.1 Laparoscopic/robotic-assisted laparoscopic cystectomy

Laparoscopic cystectomy and robotic-assisted laparoscopic cystectomy (RALC) are feasible both in male and female patients [268, 269].

Laparoscopic cystectomy is a technically challenging procedure that requires a high level of skill and has a long learning curve [270]. Recently, Aboumarzouk and co-workers conducted a systematic review in line with both Cochrane and PRISMA guidelines [271, 272]. All the included studies were observational cohort studies with no randomisation, and all reported experience with laparoscopic compared with open cystectomy [273-280]. A total of 427 patients were included: 211 underwent laparoscopic cystectomy with extracorporeal reconstruction, and 216 were included in the open cystectomy group. Patients in the laparoscopy group were significantly younger than those in the open cystectomy group. The laparoscopic group had significantly longer operative times, but less blood loss, less time to oral intake, less analgesic requirement, and shorter length of hospital stay. Patients who underwent open cystectomy developed significantly more minor complications than those treated laparoscopically. There was no difference between the two groups regarding LND yields, major complications, positive margins, pathological results, local recurrence, or distant metastases. However, there were significantly more positive nodes in the open cystectomy group. The main limitation of this meta-analysis was the inclusion of non-randomised observational studies with small patient cohorts. Only five of the studies had > 20 patients and all the studies had cohorts with < 50 patients. This led to a substantial risk of bias in the results. Another limitation was the age selection bias.

Laparoscopic cystectomy and RALC data often suffer from selection bias including younger patients, lower stage of disease, and minimal comorbidity compared to most contemporary studies of open cystectomy [281-286]. To date, laparoscopic cystectomy and RALC still need to be considered experimental because of the limited number of cases reported, absence of long-term oncological and functional outcome data, and possible selection bias [281, 287].

Laparoscopic intracorporeal construction of urinary diversion (with or without robotic assistance) has been tested in small series only [282-284, 286]. It is a challenging and lengthy procedure with the currently available equipment and must therefore be regarded as experimental. Furthermore, there are no long-term results available. Laparoscopic cystectomy and pelvic lymphadenectomy (with or without robotic assistance), with extracorporeal construction of urinary diversion, is an option for surgical treatment only in experienced centres [287] (LE: 3).

7.4.4 Urinary diversion after radical cystectomy

From an anatomical standpoint, three alternatives are currently used after cystectomy:

- Abdominal diversion, such as an ureterocutaneostomy, ileal or colonic conduit, and various forms of a continent pouch.
- Urethral diversion, which includes various forms of gastrointestinal pouches attached to the urethra as a continent, orthotopic urinary diversion (neobladder, orthotopic bladder substitution).

- Rectosigmoid diversions, such as uretero- (ileo-)rectostomy.

Different types of segments of the intestinal tract have been used to reconstruct the urinary tract, including the stomach, ileum, colon and appendix [288]. Several studies have compared certain aspects of health-related QoL, such as sexual function, urinary continence and body image, in patient cohorts with different types of urinary diversion. However, further research is needed on preoperative tumour stage and functional situation, socioeconomic status, and time interval to primary surgery.

7.4.4.1 Preparations for surgery

In consultation with the patient, both an orthotopic neobladder and ilial conduit should be considered in case reconstructive surgery exposes the patient to excessive risk (as determined by comorbidity and age).

Diagnosis of urethral tumour before cystectomy or positive urethral frozen section leads to urethrectomy and therefore excludes neobladder reconstruction. If indicated, in males, urethral frozen section has to be performed on the cysto-prostatectomy specimen just under the verumontanum and on the inferior limits of the bladder neck for females.

When there are positive lymph nodes, orthotopic neobladder can nevertheless be considered in the case of N1 involvement (metastasis in a single node in the true pelvis) but not for N2 or N3 tumours [289].

Oncological results after orthotopic neobladder substitution or conduit diversion are similar in terms of local or distant metastasis recurrence, but secondary urethral tumours seem less common in patients with neobladder compared to those with conduits or continent cutaneous diversions [290].

For cystectomy, general preparations are necessary as for any other major pelvic and abdominal surgery. If the urinary diversion is constructed from gastrointestinal segments, the length or size of the respective segments and their pathophysiology when storing urine must be considered [291]. Despite the necessary interruption and re-anastomosis of bowel, a formal bowel preparation may not be necessary [292]. Furthermore, bowel recovery time has been reduced by the use of early mobilisation, early oralisation, and gastrointestinal stimulation with metoclopramide and chewing gum [293].

Patients undergoing continent urinary diversion must be motivated to learn about their diversion and to be manually skilful in manipulating their diversion. Contraindications to more complex forms of urinary diversion include :

- debilitating neurological and psychiatric illnesses;
- limited life expectancy;
- impaired liver or renal function;
- transitional cell carcinoma of the urethral margin or other surgical margins.

Relative contraindications specific for an orthotopic neobladder are high-dose preoperative radiotherapy, complex urethral stricture disease, and severe urethral sphincter-related incontinence [294-296].

7.4.4.2 Patient selection for orthotopic diversion

Radical cystectomy and urinary diversion are the two steps of one operation. However, the literature uniformly reports the complications of radical cystectomy, while ignoring the fact that most complications are diversion related [297]. Age alone is not a criterion for offering continent diversion [296, 298]. Comorbidity, cardiac and pulmonary function, and cognitive function are all important factors that should be considered, along with the patient's social support and preference.

Age > 80 years is often considered to be the threshold after which neobladder reconstruction is not recommended, however, there is no exact age for strict contraindication. In most large series from experienced centres, the rate of orthotopic bladder substitution after cystectomy for bladder tumour is up to 80% for men and 50% for women [299-302]. Nevertheless, no randomised controlled studies comparing conduit diversion with neobladder or continent cutaneous diversion have been performed.

7.4.4.2.1 Ureterocutaneostomy

Ureteral diversion to the abdominal wall is the simplest form of cutaneous diversion. It is considered a safe procedure. It is therefore preferred in older, or otherwise compromised, patients, who need a supravescical diversion [303, 304]. However, others have demonstrated that, in carefully selected elderly patients, all other forms of wet and dry urinary diversions, including orthotopic bladder substitutions, are possible [227]. Technically, either one ureter, to which the other shorter one is attached end-to-side, is connected to the skin (transureteroureterocutaneostomy) or both ureters are directly anastomosed to the skin. Due to the smaller diameter of the ureters, stoma stenosis has been observed more often than in intestinal stomas [303].

In a retrospective comparison with short or median follow-up of 16 months, the diversion-related complication rate was considerably lower for ureterocutaneostomy compared to ileal or colon conduit [305]. Despite the limited comparative data available, however, it must be taken into consideration that older data and clinical experience suggest ureter stenosis at the skin level and ascending UTI are more frequent complications in comparison to those with ileal conduit diversion. In a retrospective study comparing various forms of intestinal diversion, ileal conduits had fewer late complications than continent abdominal pouches or orthotopic neobladders [306].

7.4.4.2.2 Ileal conduit

The ileal conduit is still an established option with well-known/predictable results. However, up to 48% of patients develop early complications including UTIs, pyelonephritis, ureteroileal leakage and stenosis [306]. The main complications in long-term follow-up studies are stomal complications in up to 24% of cases and functional and/or morphological changes of the UUT in up to 30% [307-309]. An increase in complications was seen with increased follow-up in the Berne series of 131 patients followed for a minimum of 5 years (median follow-up 98 months) [307]: the rate of complications increased from 45% at 5 years to 94% in those surviving > 15 years. In the latter group, 50% of patients developed UUT changes and 38% developed urolithiasis.

7.4.4.2.3 Continent cutaneous urinary diversion

A low-pressure detubularised ileal reservoir can be used as a continent cutaneous urinary diversion for self-catheterisation; gastric, ileocecal and sigma pouches have also been described [310-312]. Different antireflux techniques can be used [233]. Most patients have a well-functioning reservoir with day-time and night-time continence approaching 93% [313]. In a retrospective study of > 800 patients, stomal stenosis was seen in 23.5% of patients with an appendix stoma and 15% of those with an efferent intussuscepted ileal nipple [313]. Stone formation in the pouch occurred in 10% of patients [313-315]. In a small series of previously irradiated female patients, incontinence and stomal stenosis was seen in eight of 44 patients (18%) [316].

7.4.4.2.4 Ureterocolonic diversion

The oldest and most common form of ureterocolonic diversion was primarily a refluxive and later an antirefluxive connection of ureters to the intact rectosigmoid colon (uretero-rectosigmoidostomy) [317, 318]. Most indications for this procedure have become obsolete due to a high incidence of upper UTIs and the long-term risk of developing colon cancer [289, 290]. Bowel frequency and urge incontinence are additional adverse effects of this type of urinary diversion. However, it may be possible to circumvent the above-mentioned problems by interposing a segment of ileum between the ureters and rectum or sigmoid in order to augment capacity and avoid direct contact between the urothelium and colonic mucosa, as well as faeces and urine [319].

7.4.4.2.5 Orthotopic neobladder

An orthotopic bladder substitution to the urethra is now commonly used both in men and women. Contemporary reports document the safety and long-term reliability of this procedure. In several large centres, this has become the diversion of choice for most patients undergoing cystectomy [174, 226, 296]. In elderly patients (> 80 years), however, it is rarely performed, even in high-volume expert centres [320, 321].

The terminal ileum is the gastrointestinal segment most often used for bladder substitution. There is less experience with the ascending colon, including the caecum, and the sigmoid [226]. Emptying of the reservoir anastomosed to the urethra requires abdominal straining, intestinal peristalsis, and sphincter relaxation. Early and late morbidity in up to 22% of the patients is reported [322, 323]. In two studies with 1,054 and 1,300 patients [296, 324], long-term complications included diurnal (8-10%) and nocturnal (20-30%) incontinence, ureterointestinal stenosis (3-18%), metabolic disorders, and vitamin B12 deficiency. In a recent study that compared cancer control and patterns of disease recurrence in patients with neobladder and ileal conduit, there was no difference in CSS between the two groups when adjusting for pathological stage [325]. Urethral recurrence in neobladder patients seems rare (1.5-7% for both male and female patients) [296, 326]. These results indicate that neobladder in male and female patients does not compromise the oncological outcome of cystectomy. It remains debatable whether neobladder is better for QoL compared to non-continent urinary diversion [327-329].

Various forms of UUT reflux protection, including a simple isoperistaltic tunnel, ileal intussusception, tapered ileal prolongation implanted subserosally, and direct (sub)mucosal or subserosal ureteral implantation, have been described [315, 323]. According to the long-term results, the UUT is protected sufficiently by either method.

In conclusion, standard radical cystectomy in male patients with bladder neoplasms includes removal of the

entire bladder, prostate, seminal vesicles, distal ureters (segment length undefined), and corresponding lymph nodes (extent undefined) (LE: 2b). In female patients, standard radical cystectomy includes removal of the entire bladder, urethra and adjacent vagina, uterus, distal ureters, and corresponding lymph nodes.

A detailed investigation of the bladder neck prior to radical cystectomy is important for women who are scheduled for an orthotopic bladder substitute [330]. In women undergoing radical cystectomy the rate of concomitant urethral malignancy has been reported to range around 12-16% [331]. Localisation of the primary tumour at the bladder neck correlated strongly with concomitant urethral malignancy. Additionally, the tumours were at higher risk of advanced stage and nodal involvement [332].

Currently, it is not possible to recommend a particular type of urinary diversion. However, most institutions prefer ileal orthotopic neobladders and ileal conduits, based on clinical experience [333, 334]. In selected patients, f.i. patients with a single kidney, ureterocutaneostomy is surgically the least burdensome type of diversion (LE: 3). Recommendations related to radical cystectomy and urinary diversions are listed in section 7.5.

7.4.5 **Morbidity and mortality**

In two long-term studies, and one population-based cohort study, the perioperative mortality was reported as 1.2-3% at 30 days and 2.3-5.7% at 90 days [174, 297, 299, 335]. In a large single-centre series, early complications (within 3 months of surgery) were seen in 58% of patients [297]. Late morbidity is usually due to the type of urinary diversion (see also above) [300, 336]. Early morbidity associated with radical cystectomy for NMIBC (at high risk for disease progression) is similar and no less than that associated with muscle-invasive tumours [337]. In general, lower morbidity and (perioperative) mortality have been observed by surgeons and in hospitals with a higher caseload and therefore more experience [338-341].

Table 7.1: Management of neobladder morbidity (30-64%) [342].

CLAVIEN System		Morbidity	Management
Grade I	Any deviation from the normal postoperative course without the need for pharmacological treatment or surgical, endoscopic and radiological interventions. Allowed therapeutic regimens are: drugs such as antiemetics, antipyretics, analgetics, diuretics and electrolytes and physiotherapy. This grade also includes wound infections opened at the bedside.	Immediate complications:	
		Post-operative ileus	Nasogastric intubation (usually removed at J1) Chewing gum Avoid fluid excess and hypovolemia (provoke splanchnic hypoperfusion)
		Postoperative Nausea and Vomiting	Antiemetic agent (decrease opioids) Nasogastric intubation
		Urinary infection	ATB, no ureteral catheter removal Check the 3 drainages (ureters and neobladder)
		Ureteral catheter (UC) obstruction	5cc saline UC injection to avoid the obstruction Increase volume infusion to increase diuresis
		Intra abdominal urine leakage (anastomosis leakage)	Check drainages and watchful waiting
		Anaemia well tolerated	Martial treatment (give iron supplement)
		Late complications:	
		Non compressive lymphocele	Watchful waiting
		Mucus cork	Cough Indwelling catheter to remove the obstruction

		Incontinence	Urine analysis (infection), echography (post-void residual) Physiotherapy
		Retention	Drainage and self- catheterisation education
Grade II	Requiring pharmacological treatment with drugs other than those allowed for grade I complications. Blood transfusions and total parenteral nutrition are also included.	Anaemia badly tolerated or if myocardial cardiopathy history	Transfusion
		Pulmonary embolism	Heparinotherapy
		Pyelonephritis	ATB and check kidney drainage (nephrostomy if necessary)
		Confusion or neurological disorder	Neuroleptics and avoid opioids
Grade III	Requiring surgical, endoscopic or radiological intervention	UC accidentally dislodged	Indwelling leader to raise the UC
		Anastomosis stenosis (7%)	Renal drainage (ureteral catheter or nephrostomy)
		Ureteral reflux	No treatment if asymptomatic
III-a	Intervention not under general anaesthesia	Compressive lymphocele	Transcutaneous drainage or intraoperative marsupialisation (cf grade III)
III-b	Intervention under general anaesthesia	Ileal anastomosis leakage	Ileostomy ASAP
		Evisceration	Surgery in emergency
		Compressive lymphocele	Surgery (marsupialisation)
Grade IV	Life-threatening complication (including CNS complications: brain haemorrhage, ischaemic stroke, subarachnoid bleeding, but excluding transient ischaemic attacks) requiring IC/ICU management.	Rectal necrosis	Colostomy
		Neobladder rupture	Nephrostomy and indwelling catheter / surgery for repairing neobladder
		Severe sepsis	ATB and check all the urinary drainages and CT Scan in emergency
IV-a	Single organ dysfunction (including dialysis)	Non obstructive renal failure	Bicarbonate / aetiology treatment
IV-b	Multi-organ dysfunction	Obstructive pyelonephritis and septicaemia	Nephrostomy and ATB
Grade V	Death of a patient		
Suffix 'd'	<i>If the patient suffers from a complication at the time of discharge, the suffix "d" (for 'disability') is added to the respective grade of complication. This label indicates the need for a follow-up to fully evaluate the complication.</i>		

ASAP = as soon as possible; ATB = antibiotics; CNS = central nervous system; CT = computed tomography; IC = intensive care; ICU = intensive care unit; UC = urethral catheter.

7.4.6 Survival

According to a multi-institutional database of 888 consecutive patients undergoing radical cystectomy for BC, the 5-year recurrence-free survival was 58% and the CSS was 66% [343]. Recent external validation of postoperative nomograms for bladder-cancer-specific mortality showed similar results, with bladder-cancer-specific survival of 62% [344].

Recurrence-free survival and OS in a large single-centre study of 1,054 patients was 68% and 66% at 5 years and 60% and 43%, at 10 years, respectively [164]. However, the 5-year recurrence-free survival in node-positive patients who underwent cystectomy was considerably less at 34-43% [163, 164, 345]. In a surgery-only study, the 5-year recurrence-free survival was 76% in patients with pT1 tumours, 74% for pT2, 52% for pT3, and 36% for pT4 [164].

A trend analysis according to the 5-year survival and mortality rates of BC in the United States, between 1973 and 2009 with a total of 148,315 BC patients, revealed an increased stage-specific 5-year survival rate for all stages, except for metastatic disease [8].

7.4.7 Conclusions and recommendations for radical cystectomy and urinary diversion

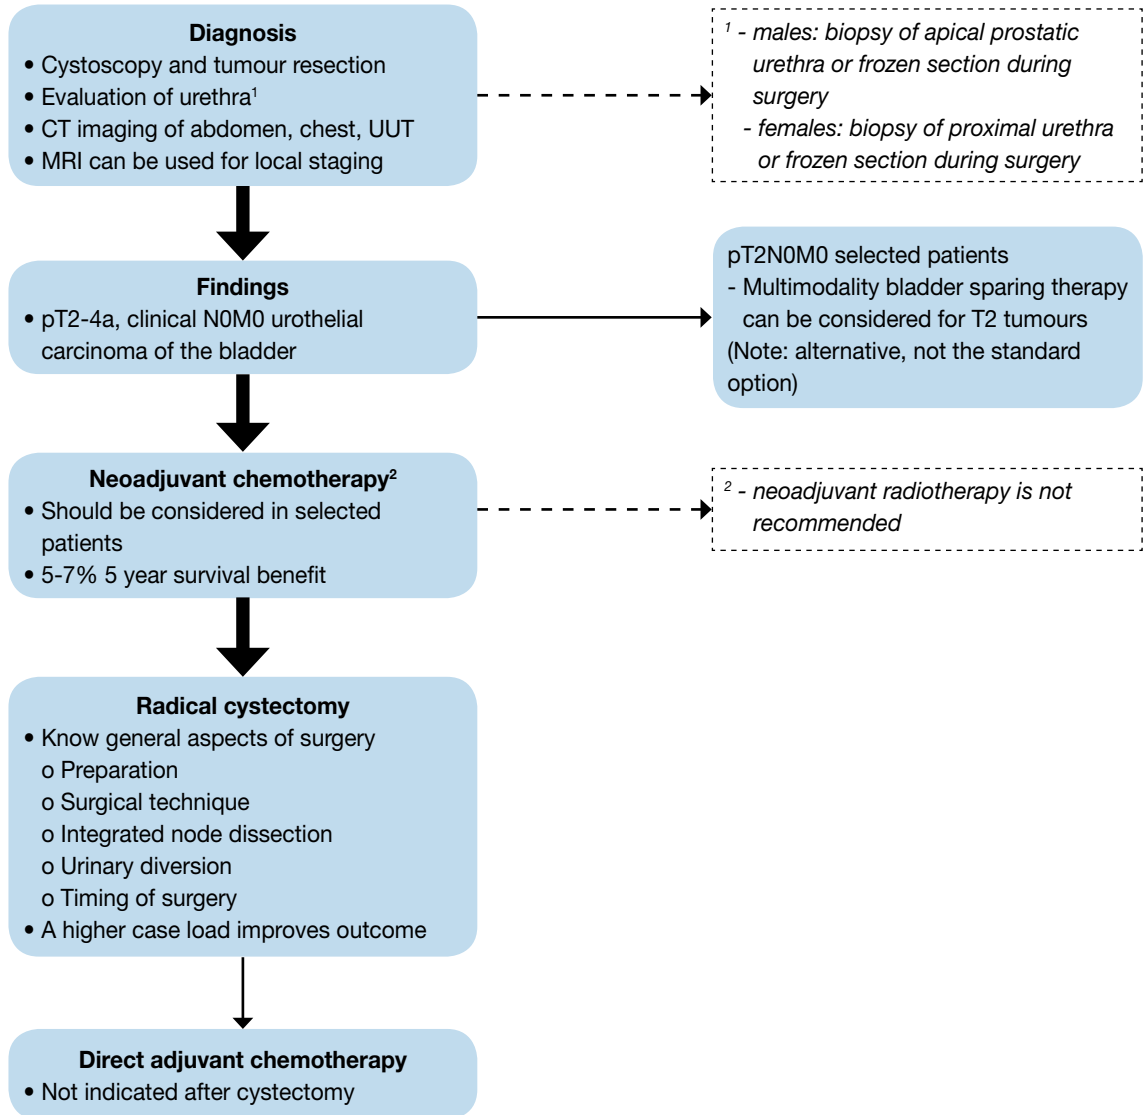

Conclusions	LE
For MIBC, radical cystectomy is the curative treatment of choice.	3
A higher case load reduces morbidity and mortality of cystectomy.	3
Radical cystectomy includes removal of regional lymph nodes.	3
There are data to support that extended LND (vs. standard or limited LND) improves survival after radical cystectomy.	3
Radical cystectomy in both sexes must not include removal of the entire urethra in all cases, which may then serve as the outlet for an orthotopic bladder substitution. The terminal ileum and colon are the intestinal segments of choice for urinary diversion.	3
The type of urinary diversion does not affect oncological outcome.	3
Laparoscopic cystectomy and robotic-assisted laparoscopic cystectomy are feasible but still investigational. Current best practice is open radical cystectomy.	3
In patients aged > 80 years with MIBC, cystectomy is an option.	3
Surgical outcome is influenced by comorbidity, age, previous treatment for bladder cancer or other pelvic diseases, surgeon and hospital volumes of cystectomy, and type of urinary diversion.	2
Surgical complications of cystectomy and urinary diversion should be reported using a uniform grading system. Currently, the best-adapted, graded system for cystectomy is the Clavien grading system.	2
No conclusive evidence exists as to the optimal extent of LND.	2a

Recommendations	GR
Do not delay cystectomy for > 3 months because it increases the risk of progression and cancer-specific mortality.	B
Before cystectomy, the patient should be fully informed about the benefits and potential risks of all possible alternatives, and the final decision should be based on a balanced discussion between patient and surgeon.	B
An orthotopic bladder substitute or ileal conduit diversion should be offered to male and female patients lacking any contraindications and who have no tumour in the urethra or at the level of urethral dissection.	B
Preoperative radiotherapy is not recommended in subsequent cystectomy with urinary diversion.	A
Pre-operative bowel preparation is not mandatory. "Fast track" measurements may reduce the time of bowel recovery.	C
Radical cystectomy is recommended in T2-T4a, N0 M0, and high-risk non-MIBC (as outlined above).	A*
Lymph node dissection must be an integral part of cystectomy.	A
The urethra can be preserved if margins are negative. If no bladder substitution is attached, the urethra should be checked regularly.	B
Laparoscopic cystectomy and robot-assisted laparoscopic cystectomy are both management options. However, current data have not sufficiently proven the advantages or disadvantages for oncological and functional outcomes.	C

*Upgraded following EAU Working Panel consensus.

GR = grade of recommendation; LE = level of evidence; LND = lymph node dissection; MIBC = muscle-invasive bladder cancer.

Figure 7.1: Flowchart for the management of T2-T4a N0M0 urothelial bladder cancer

CT = computed tomography; MRI = magnetic resonance imaging; UUT = upper urinary tract.

7.5. Unresectable tumours

7.5.1 Palliative cystectomy for muscle-invasive bladder carcinoma

Locally advanced tumours (T4b, invading the pelvic or abdominal wall) may be accompanied by several debilitating symptoms, including bleeding, pain, dysuria and urinary obstruction. These patients are candidates for palliative treatments, such as palliative radiotherapy. Palliative cystectomy with urinary diversion carries the greatest morbidity and should be considered for symptom relief only if there are no other options [346-348].

Locally advanced MIBC can be associated with ureteral obstruction due to a combination of mechanical blockage by the tumour and invasion of ureteral orifices by tumour cells. In a series of 61 patients with obstructive uraemia, radical cystectomy was not an option in 23 patients, and obstruction was relieved using permanent nephrostomy tubes [349]. Another 10 patients underwent palliative cystectomy, but local pelvic recurrence occurred in all 10 patients within the first year of follow-up. Another small (n = 20) study showed that primary cystectomy for T4 BC was technically feasible and associated with a very tolerable therapy-related morbidity and mortality [350].

7.5.1.1 Recommendations for unresectable tumours

Recommendations	GR
In patients with inoperable locally advanced tumours (T4b), primary radical cystectomy is a palliative option.	B
In patients with symptoms, palliative cystectomy may be offered.	

GR = grade of recommendation.

7.5.2 Supportive care

7.5.2.1 Obstruction of the UUT

Unilateral (best kidney) or bilateral nephrostomy tubes provide the easiest solution for UUT obstruction, but patients find the tubes inconvenient and prefer ureteral stenting. However, stenting can be difficult to achieve, stents must be regularly replaced and there is the risk of stent obstruction or displacement. Another possible solution is a urinary diversion with, or without, a palliative cystectomy.

7.5.2.2 Bleeding and pain

In the case of bleeding, the patient must first be screened for coagulation disorders or the patient's use of anticoagulant drugs must be reviewed. Transurethral (laser) coagulation may be difficult in a bladder full of tumour or with a bleeding tumour. Intravesical rinsing of the bladder with 1% silver nitrate or 1-2% alum can be effective [351]. It can usually be done without any anaesthesia. The instillation of formalin (2.5-4% during 30 minutes) is a more aggressive and more painful procedure, requiring anaesthesia. Formalin instillation has a higher risk of side-effects, e.g. bladder fibrosis, but is more likely to control the bleeding [351]. Vesicoureteral reflux should be excluded to prevent renal complications.

Radiation therapy is another common strategy for control of bleeding, and is also used to control pain. An older study reported control of haematuria in 59% of patients and pain control in 73% [352]. Irritative bladder and bowel complaints due to irradiation are possible, but are usually mild. Non-conservative options are embolisation of specific arteries in the small pelvis, with success rates as high as 90% [351]. Radical surgery is a last resort and includes cystectomy and diversion (see above Section 7.5.1).

7.6 Bladder-sparing treatments for localised disease

7.6.1 Transurethral resection of bladder tumour (TURB)

TURB alone in patients with muscle-invasive bladder tumours is only possible as a therapeutic option if tumour growth is limited to the superficial muscle layer and if re-staging biopsies are negative for residual (invasive) tumour [353]. In general about half will still have to undergo radical cystectomy for recurrent muscle-invasive cancer with a disease-specific mortality rate of up to 47% within this group [354]. A disease-free status at re-staging TURB appears to be crucial in making the decision not to perform radical cystectomy [355, 356]. A prospective study by Solsona et al., which included 133 patients with a radical TURB and re-staging negative biopsies, has recently reported a 15-year follow-up [356]. 30% had recurrent NMIBC and went on to intravesical therapy, and 30% (n = 40) progressed, of which 27 died of BC. After 5, 10 and 15 years the results showed a CSS of 81.9%, 79.5%, and 76.7%, and a progression-free survival (PFS) with an intact bladder of 75.5%, 64.9%, and 57.8%, respectively.

In conclusion, TURB alone should only be considered as a therapeutic option for muscle-invasive disease after radical TURB, when the patient is unfit for cystectomy or a multimodality bladder-preserving approach, or refuses open surgery [357].

7.6.1.2 Recommendation for transurethral resection of bladder tumour

Recommendation	LE	GR
Transurethral resection of bladder tumour alone is not a curative treatment option in most patients.	2a	B

GR = grade of recommendation; LE = level of evidence.

7.6.2 External beam radiotherapy (EBRT)

The target field usually comprises the bladder only, with a safety margin of 1.5-2 cm to allow for unavoidable organ movements [358]. Any beneficial effect with larger pelvic fields has not been demonstrated. The target dose for curative radiotherapy for BC is 60-66 Gy, with a subsequent boost using external radiotherapy or interstitial brachytherapy. The course of radiotherapy should not extend beyond 6-7 weeks to minimise the repopulation of cancer cells [359, 360]. The use of modern standard radiotherapy techniques results in major,

related, late morbidity of the urinary bladder or bowel in less than 5% of tumour-free patients [361]. As well as the response to radiotherapy, important prognostic factors for outcome include tumour size, hydronephrosis and completeness of the initial TURB. Additional prognostic factors found in a recent single institution study (n = 459, including 30% of unfit T1 patients) were age and stage [362]. Overall, 5-year survival rates in patients with MIBC range between 30% and 60%, depending on whether they show a complete response (CR) following radiotherapy. Cancer-specific survival rates are between 20% and 50% [360, 363-365]. Similar long-term results were reported by Chung et al. [366]. A total of 340 patients with MIBC were treated with EBRT alone, EBRT with concurrent chemotherapy, or neoadjuvant chemotherapy followed by EBRT. The overall CR was 55% and the 10-year DSS and OS were 35% and 19%, respectively. Complete response was 64% after EBRT alone, 79% after concurrent chemotherapy (n = 36), and 52% after neoadjuvant chemotherapy (n = 57). Younger age, lower tumour stage and absence of CIS were associated with a significant improvement in survival.

Based on available trials, a Cochrane analysis has demonstrated that radical cystectomy has an OS benefit compared to radiotherapy [367].

Similar long-term results were reported by Chung et al. [366]. A total of 340 patients with MIBC were treated with EBRT alone, EBRT with concurrent chemotherapy, or neoadjuvant chemotherapy followed by EBRT. The overall CR was 55% and the 10-year DSS and OS were 35% and 19%, respectively. Complete response was 64% after EBRT alone, 79% after concurrent chemotherapy (n = 36), and 52% after neoadjuvant chemotherapy (n = 57). Younger age, lower tumour stage and absence of CIS were associated with a significant improvement in survival.

In conclusion, EBRT can be an alternative treatment in patients unfit for radical surgery.

7.6.2.1 Conclusions and recommendation for external beam radiotherapy

Conclusions	LE
External beam radiotherapy alone should only be considered as a therapeutic option when the patient is unfit for cystectomy or a multimodality bladder-preserving approach.	3
Radiotherapy can also be used to stop bleeding from the tumour when local control cannot be achieved by transurethral manipulation due to extensive local tumour growth.	3

Recommendation	GR
Radiotherapy alone is not recommended as primary therapy for localised bladder cancer.	B

GR = grade of recommendation; LE = level of evidence.

7.6.3 Chemotherapy

Chemotherapy alone rarely produces durable CRs. In general, a clinical CR rate of up to 56%, as reported in some series, must be weighed against a staging error of > 60% [368, 369]. Response to chemotherapy is a prognostic factor for treatment outcome and eventual survival [184], though it may be confounded by patient selection.

Several groups have reported the effect of chemotherapy on resectable tumours (neoadjuvant approach), as well as unresectable primary tumours [182, 211, 370, 371]. Neoadjuvant chemotherapy with 2-3 cycles of methotrexate, vinblastine, adriamycin plus cisplatin (MVAC) or cisplatin, methotrexate plus vinblastine (CMV) has led to a down-staging of the primary tumour in different prospective series [182, 211, 370]. Pathological complete responses of primary bladder tumours were reached in 12-50% of patients after MVAC and in 12-22% of patients after gemcitabine/cisplatin (GC) in phase II and phase III trials [182, 211, 370, 372-379]. Contemporary series with GC followed by radical cystectomy reported inferior pT0 rates, which may have been related to a lack of dose density and inappropriate delay of surgery [215].

For highly selected patients, a bladder-conserving strategy with TURB and systemic cisplatin-based chemotherapy, preferably with MVAC, may allow long-term survival with intact bladder [184]. However, this approach cannot be recommended for routine use.

7.6.3.1 Conclusion and recommendation for chemotherapy for muscle-invasive bladder tumours

Conclusion	LE
With cisplatin-based chemotherapy as primary therapy for locally advanced tumours in highly selected patients, complete and partial local responses have been reported.	2b

Recommendation	GR
Chemotherapy alone is not recommended as primary therapy for localised bladder cancer.	A

GR = grade of recommendation; LE = level of evidence.

7.6.4 Multimodality bladder-preserving treatment

Multimodality treatment (MMT) or trimodality treatment combines TURB, chemotherapy and radiation. The rationale for performing TURB and radiation is to achieve local tumour control. The addition of systemic chemotherapy or other radiosensitisers (mentioned below) aims at the potentiation of radiotherapy.

Micrometastasis is targeted by platinum-based combination chemotherapy which is covered in Section 7.2 on neoadjuvant chemotherapy. The aim of multimodality therapy is to preserve the bladder and QoL, without compromising outcome. A collaborative review addressed this approach [380].

There are no completed randomised controlled trials to compare the outcome of MMT with the gold standard, radical cystectomy. Many of the reported series have differing characteristics to the large surgical series which typically have median ages in the mid-late 60s compared to mid-70s for some large radiotherapy series (reviewed in [381]). In the case of MMT, two distinct patterns of care may be distinguished: treatment aimed at patients fit for cystectomy and treatment aimed at older, less fit patients. For the former category, MMT is a selective bladder preservation option. In that case the initial step is a radical TURB, where as much tumour as possible should be resected. This implies that appropriate patient selection (T2 tumours, no CIS) is critical [382]. For patients who are not candidates for cystectomy, less stringent criteria can be applied, although extensive CIS and poor bladder function should both be regarded as strong contraindications.

Following TURBT and staging, treatment then comprises EBRT with concurrent radiosensitising drugs. Two schedules are in common use worldwide: a split dose format with interim cystoscopy is used in North America [383], whilst single phase treatment is more commonly used elsewhere (reviewed in [381]). A typical schedule for single phase radiotherapy would be either 64-66 Gy in 32-33 fractions or 55 Gy in 20 fractions, generally to the bladder plus tumour only. For radiosensitising chemotherapy cisplatin [383] or mitomycin C plus 5-fluorouracil [381] can be used, but other schedules have also been used. In particular, hypoxic cell sensitisation with nicotinamide and carbogen has been evaluated in a large phase 3 trial [384]. With MMT, 5-year CSS and OS rates of 50% to 82% and from 36% to 74% were achieved, respectively [361, 381, 383-387]. Salvage cystectomy rates are 10-30% [381, 383, 387]. There are data to show that major complication rates are similar for salvage and primary cystectomy [388]. The majority of recurrences post-MMT are non-invasive and can be managed conservatively [381].

The collaborative review came to the conclusion that there are accumulating data to suggest that bladder preservation with MMT leads to acceptable outcomes and therefore may be considered a reasonable treatment option in well-selected patients as compared to radical cystectomy. It should also be considered in all patients where surgery is contraindicated, either relatively or absolutely as the factors that determine fitness for surgery and chemoradiotherapy differ.

A bladder-preserving multimodality strategy requires very close multidisciplinary co-operation and a high level of patient compliance. Even if a patient has shown a CR to a multimodality bladder-preserving strategy, the bladder remains a potential source of recurrence, hence long-term bladder monitoring is essential and patient counselling is required.

7.6.4.1 Conclusions and recommendations for multimodality treatment in MIBC

Conclusions	LE
In a highly selected patient population, long-term survival rates of multimodality treatment are comparable to those of early cystectomy.	3
Delay in surgical therapy can compromise survival rates.	2b

Recommendations	GR
Surgical intervention or multimodality treatments are the preferred curative therapeutic approaches as they are more effective than radiotherapy alone.	B
Multimodality treatment could be offered as an alternative in selected, well-informed and compliant patients, especially for whom cystectomy is not an option.	B

GR = grade of recommendation; LE = level of evidence.

7.7 Adjuvant chemotherapy

Adjuvant chemotherapy after radical cystectomy for patients with pT3/4 and/or lymph node positive (N+) disease without clinically detectable metastases (M0) is under debate [389, 390] and still infrequently used [178].

The general benefits of adjuvant chemotherapy include:

- Chemotherapy is administered after accurate pathological staging, therefore treatment in patients at low risk for micrometastases is avoided;
- No delay in definitive surgical treatment.

The drawbacks of adjuvant chemotherapy are:

- Assessment of in vivo chemosensitivity of the tumour is not possible and overtreatment is an unavoidable problem;
- Delay or intolerability of chemotherapy, due to postoperative morbidity [391].

There is limited evidence from adequately conducted and accrued randomised phase III trials in favour of the routine use of adjuvant chemotherapy [390, 392-397]. Individual patient data from six randomised trials [398-402] of adjuvant chemotherapy were included in one meta-analysis [392] with 491 patients for survival analysis (unpublished data from Otto et al, were included in the analysis). All these trials were suboptimal with serious deficiencies, including small sample size (underpowered), early cessation of patient entry, and flaws in design and statistical analysis, including irrelevant endpoints or a lack of recommendations concerning salvage chemotherapy for relapse or metastases [390]. In these trials, three or four cycles of CMV (cisplatin, methotrexate and vinblastine), CISCA (cisplatin, cyclophosphamide, and adriamycin), MVA(E)C (methotrexate, vinblastine, adriamycin or epirubicin, and cisplatin) and CM (cisplatin and methotrexate) were used [403], and one trial used cisplatin monotherapy [401]. These data were not convincing enough to give an unequivocal recommendation for the use of adjuvant chemotherapy.

In a more recent meta-analysis [393], an additional three studies were included [394-396]. However, the patient number in this meta-analysis of nine trials was only 945, and none of the trials were fully accrued and no individual patient data were used [393]. For one trial, only an abstract was available at the time of the meta-analysis [395], and none of the included trials by themselves were significantly positive for overall survival (OS) in favour of adjuvant chemotherapy. In two of the trials, more modern chemotherapy regimens were used (gemcitabine/cisplatin and paclitaxel/gemcitabine and cisplatin) [394, 395]. The hazard ratio (HR) for OS was 0.77 and there was a trend towards an OS benefit when including all nine trials. The effect was stronger for disease-free survival (DFS) (HR: 0.66; 95% CI: 0.48-0.92) and when stratified for the ratio of nodal positivity (HR: 0.64; 95% CI: 0.45- 0.91). The background of this finding was a heterogeneity in outcomes observed between the included studies. After stratification of the studies by the ratio of node positivity, no further heterogeneity was identified. The HR for DFS associated with adjuvant cisplatin-based chemotherapy in studies with higher nodal involvement was 0.39 (95% CI: 0.28-0.54), compared with 0.89 (95% CI: 0.69-1.15) in studies with less nodal involvement.

Furthermore, a retrospective cohort analysis that included 3,974 patients after cystectomy and lymph node dissection showed an OS benefit in high-risk subgroups (extravesical extension and nodal involvement) [HR: 0.75; CI 0.62-0.90] [404]. The most recent publication of the so far largest RCT (EORTC 30994), although not fully accrued, showed a significant improvement of PFS for immediate compared with deferred treatment (HR 0.54, 95% CI 0.4-0.73, $p < 0.0001$), there was, however, no significant OS benefit [405].

From the currently available evidence, it is still unclear whether immediate adjuvant chemotherapy or chemotherapy at the time of relapse is superior, or if the two approaches are equivalent with respect to the endpoint of OS. Cisplatin-based combination chemotherapy results in long-term DFS, even in metastatic disease, mainly in patients with lymph node metastases only, and with a good performance status [376, 406, 407]. With the most recent meta-analysis, the positive role of adjuvant chemotherapy for BC has been strengthened, however, still with a poor level of evidence [393]. Patients should be informed about potential chemotherapy options before radical cystectomy, including neoadjuvant and adjuvant chemotherapy, and the limited evidence for adjuvant chemotherapy.

7.7.1 Recommendations for adjuvant chemotherapy

Recommendations	GR
Adjuvant cisplatin-based combination chemotherapy can be offered to patients with pT3/4 and/or pN+ disease if no neoadjuvant chemotherapy has been given.	C

GR = grade of recommendation.

7.8 Metastatic disease

7.8.1 Introduction

Half of the patients with muscle-invasive urothelial cancer (UC) relapse after radical cystectomy, depending on the pathological stage of the primary tumour and the nodal status. Local recurrence accounts for 30% of relapses, whereas distant metastases are more common. Ten to fifteen percent of patients are already metastatic at diagnosis [408]. Before the development of effective chemotherapy, patients with metastatic urothelial cancer rarely had a median survival that exceeded 3-6 months [409].

7.8.1.1 Prognostic factors and treatment decisions

Prognostic factors are crucial for assessing phase II study results and stratifying phase III trials [374, 410]. In a multivariate analysis, Karnofsky performance status (PS) of $\leq 80\%$ and presence of visceral metastases were independent prognostic factors of poor survival after treatment with MVAC (methotrexate, vinblastine, adriamycin and cisplatin [378]. They have also been validated for newer combination chemotherapy regimens [411-413].

For patients refractory to, or progressing shortly after, platinum-based combination chemotherapy, four prognostic groups have been established, based on three adverse factors that have been developed in patients treated with vinflunine and that have been validated in an independent data set: Hb < 10 g/dL; presence of liver metastases; and ECOG PS ≥ 1 [414]. Cisplatin, using different schedules, has also been administered in patients with a GFR down to 40 mL/min. The respective studies were mostly small sized phase I and II trials [415-418]. One phase III trial used a cut off for cisplatin eligibility of ≥ 50 mL/min [419].

7.8.1.2 Comorbidity in metastatic disease

Comorbidity is defined as “the presence of one or more disease(s) in addition to an index disease” (see Section 6.2.1). Comorbidity increases with age. However, chronological age does not necessarily correlate with functional impairment. There are several definitions by which patients can be selected as potentially fit or unfit for chemotherapy, but age is not among them [420].

7.8.1.3 Not eligible for cisplatin (unfit)

The European Organisation for Research and Treatment of Cancer (EORTC) conducted the first randomised phase II/III trial for urothelial carcinoma patients who were unfit for cisplatin chemotherapy [421]. The EORTC definitions were GFR < 60 mL/min and/or PS 2.

An international survey among BC experts [422] was the basis for a consensus statement on how to classify patients unfit for cisplatin-based chemotherapy. At least one of the following criteria has to be present: PS > 1 ; GFR ≤ 60 mL/min; grade ≥ 2 audiometric loss and peripheral neuropathy; and New York Heart Association (NYHA) class III heart failure [423].

More than 50% of patients with urothelial cancer are not eligible for cisplatin-based chemotherapy [424-427].

Renal function assessment in UC is of utmost importance for treatment selection. Calculation of creatinine clearance (CrCl) (24-h urine collection) with current formulae tend to underestimate clearance in patients aged > 65 years compared to measured CrCl [424, 428].

7.8.2 Single-agent chemotherapy

Response rates to single-agent, first-line chemotherapy vary. The most robust data have shown a response rate of about 25% for first- and second-line gemcitabine in several phase II trials [429, 430]. Responses with single agents are usually short-lived, complete responses are rare and no long-term disease-free survival has been reported. The median survival in such patients is only 6-9 months.

7.8.3 Standard first-line chemotherapy for fit patients

Cisplatin-containing combination chemotherapy has been the standard of care since the late 1980s (for a review see [431]). MVAC and gemcitabine/cisplatin (GC) prolonged survival to up to 14.8 and 13.8 months, respectively, compared to monotherapy and older combinations. Neither of the two combinations is superior to the other, but equivalence has not been tested. Response rates were 46% and 49% for MVAC and GC, respectively. The long-term survival results have confirmed the anticipated equivalence of the two regimens [406]. The major difference between the above-mentioned combinations is toxicity. The lower toxicity of GC [146] has resulted in it becoming a new standard regimen [432]. MVAC is better tolerated when combined with granulocyte colony-stimulating factor (G-CSF) [432, 433].

High-dose intensity MVAC (HD-MVAC) with G-CSF is less toxic and more efficacious than standard MVAC in terms of dose density, complete response, and 2-year survival rate. However, there is no significant difference in median survival between the two regimens [434, 435].

In general, all disease sites have been shown to respond to cisplatin-based combination chemotherapy. A response rate of 66% and 77% with MVAC and HD-MVAC, respectively, has been reported in retroperitoneal lymph nodes versus 29% and 33% at extranodal sites [434]. The disease sites also have an impact on long-term survival. In lymph-node-only disease, 20.9% of patients were alive at 5 years compared to only 6.8% of patients with visceral metastases [406].

Further intensification of treatment using the new PCG triple regimen (paclitaxel, cisplatin and gemcitabine) did not result in a significant improvement in OS in the intent-to-treat (ITT) population of a large randomised phase III trial, comparing PCG triple regimen to GC [436]. However, the overall response rate (ORR) was higher with the triple regimen (56% vs. 44%; $P = 0.0031$), and the trend for OS improvement in the ITT population (15.8 vs. 12.7 months; HR = 0.85, $P = 0.075$) became significant in the eligible population. Adding paclitaxel to GC did not induce major additional side effects. G4 neutropenia was more common (35.8% vs. 20% for GC), as was febrile neutropenia (13.2% vs. 4.3%), and the need for G-CSF was higher (17% vs. 11%). GC alone caused more grade 4 thrombocytopenia and thrombocytopenia-induced bleeding (11.4% vs. 6.8%). PCG is one additional option for first-line treatment of UC.

7.8.4 Carboplatin-containing chemotherapy for fit patients

Carboplatin-containing chemotherapy is not equivalent to cisplatin combinations, and should not be considered interchangeable or standard. Several randomised phase II trials of carboplatin versus cisplatin combination chemotherapy have produced lower CR rates and shorter OS for the carboplatin arms [437].

7.8.5 Non-platinum combination chemotherapy

Different combinations of gemcitabine and paclitaxel have been studied as first- and second-line treatments. Apart from severe pulmonary toxicity with a weekly schedule of both drugs, this combination is well tolerated and produces response rates between 38% and 60% in both lines. Non-platinum combination chemotherapy has not been compared to standard cisplatin chemotherapy in randomised trials, therefore, it is not recommended for first-line use in cisplatin eligible patients [438-445].

7.8.6 Chemotherapy in patients unfit for cisplatin

Up to 50% of patients are ineligible for cisplatin-containing chemotherapy [423]. The first randomised phase II/III trial in this setting was conducted by the EORTC and compared methotrexate/carboplatin/vinblastine (M-CAVI) and carboplatin/gemcitabine (GemCarbo) in patients unfit for cisplatin. Both regimens were active. Severe acute toxicity (SAT) was 13.6% in patients treated with GemCarbo versus 23% with M-CAVI, while the ORR was 42% for GemCarbo and 30% for M-CAVI. Further analysis showed that in patients with PS 2 and impaired renal function, combination chemotherapy provided limited benefit [421]. The ORR and SAT were both 26% for the former group, and 20% and 24%, respectively, for the latter group [421]. Recent phase III data have confirmed these results [413].

7.8.7 Second-line treatment

Second-line chemotherapy data are highly variable and prognostic factors have been established recently (see Section 7.8.1.1) [414]. A reasonable strategy may be to re-challenge former cisplatin-sensitive patients if progression occurs at least 6-12 months after first-line cisplatin-based combination chemotherapy.

Second-line response rates of paclitaxel (weekly), docetaxel, nab-paclitaxel [446] oxaliplatin, ifosfamide, topotecan, pemetrexed, lapatinib, gefitinib and bortezomib have ranged between 0% and 28% in small phase II trials [430]. Although gemcitabine has also shown excellent response rates in second-line use, most patients already receive this drug as part of their front-line treatment [429].

Paclitaxel/gemcitabine studies have shown response rates of 38-60%. No randomised phase III trial with an adequate comparator arm has been conducted to assess the true value and OS benefit of this second-line combination [409, 444, 447].

Vinflunine, a novel third-generation vinca alkaloid, provided promising results in phase II trials [448]. A randomised phase III trial compared vinflunine plus best supportive care (BSC) against BSC alone in patients progressing after first-line treatment with platinum-containing combination chemotherapy for metastatic disease [449]. The results showed a modest ORR (8.6%), a clinical benefit with a favourable safety profile and, most importantly, a survival benefit in favour of vinflunine, which was statistically significant in the eligible patient population (not in the ITT population). For second-line treatment of advanced or metastatic urothelial cancer, this trial reached the highest level of evidence ever reported. Currently, vinflunine is the only approved second-line treatment.

7.8.8 **Low-volume disease and post-chemotherapy surgery**

With cisplatin-containing combination chemotherapy, excellent response rates may be obtained in patients with lymph node but no other metastases, good PS, and adequate renal function, including a high number of CRs, with up to 20% of patients achieving long-term disease-free survival [406, 435, 450, 451]. The role of surgery after chemotherapy is still unclear. Although some studies suggest a survival benefit and QOL improvement, the level of evidence supporting this practice is very limited [452-466]. A retrospective study of post-chemotherapy surgery after a partial or complete response has indicated that surgery may contribute to long-term disease-free survival in selected patients [379, 467, 468].

7.8.9 **Treatment of bone metastases**

The prevalence of metastatic bone disease (MBD) in patients with advanced/metastatic urothelial cancer is 30-40% [469]. Skeletal complications due to MBD have a detrimental effect on pain and QoL and are also associated with increased mortality [470]. Bisphosphonates reduce and delay skeletal-related events (SREs) due to bone metastases by inhibiting bone resorption. In a small pilot study in patients with BC, SREs caused by bone metastases were delayed [471]. Denosumab is a fully human monoclonal antibody that binds to and neutralises RANKL (receptor activator of nuclear factor- κ B ligand), thereby inhibiting osteoclast function and preventing generalised bone resorption and local bone destruction. Denosumab is not inferior to zoledronic acid (ZA) in preventing or delaying SREs in patients with advanced MBD, including patients with urothelial carcinoma [472]. Denosumab has recently been approved by the European Medicines Agency (EMA) for treatment of patients with bone metastases from solid tumours. Patients with MBD, irrespective of the cancer type, should be considered for bone-targeted treatment [470].

Patients treated with ZA or denosumab should be informed about possible side effects and receive prophylactic treatment for jaw osteonecrosis and hypocalcaemia, which is more common with denosumab. Aggressive calcium and vitamin D supplementation is recommended. Dosing regimens of ZA should follow regulatory recommendations and should be adjusted according to pre-existing medical conditions [473]. For denosumab, no dose adjustments are required for variations in renal function.

7.8.10 **Conclusions and recommendations for metastatic disease**

Conclusions	LE
In a first-line setting, PS and the presence or absence of visceral metastases are independent prognostic factors for survival.	1b
In a second-line setting, negative prognostic factors are: liver metastasis, PS \geq 1 and low haemoglobin (< 10 g/dL).	1b
Cisplatin-containing combination chemotherapy can achieve median survival of up to 14 months, with long-term disease-free survival reported in ~15% of patients with nodal disease and good PS.	1b
Single-agent chemotherapy provides low response rates of usually short duration.	2a
Carboplatin combination chemotherapy is less effective than cisplatin-based chemotherapy in terms of complete response and survival.	2a
Non-platinum combination chemotherapy produces substantial responses in first- and second-line settings.	2a
Non-platinum combination chemotherapy has not been tested against standard chemotherapy in patients who are fit or unfit for cisplatin combination chemotherapy.	4
There is no defined standard chemotherapy for unfit patients with advanced or metastatic urothelial cancer.	2b
Vinflunine reaches the highest level of evidence ever reported for second-line use.	1b
Post-chemotherapy surgery after partial or complete response may contribute to long-term disease-free survival.	3
Zoledronic acid and denosumab have been approved for all cancer types including urothelial cancer, because they reduce and delay skeletal related events in metastatic bone disease.	1b

Recommendations	GR
<i>First-line treatment for fit patients:</i>	
Use cisplatin-containing combination chemotherapy with GC, PCG, MVAC, preferably with G-CSF, or HD-MVAC with G-CSF.	A
Carboplatin and non-platinum combination chemotherapy is not recommended.	B
<i>First-line treatment in patients ineligible (unfit) for cisplatin:</i>	
Use carboplatin combination chemotherapy or single agents.	C
For cisplatin-ineligible (unfit) patients, with PS2 or impaired renal function, as well as those with 0 or 1 poor Bajorin prognostic factors and impaired renal function, treatment with carboplatin-containing combination chemotherapy, preferably with gemcitabine/carboplatin is indicated.	B
<i>Second-line treatment:</i>	
In patients progressing after platinum-based combination chemotherapy for metastatic disease, vinflunine should be offered. Alternatively, treatment within a clinical trial setting may be offered.	A*
Zoledronic acid or denosumab is recommended for treatment of bone metastases.	B

* Grade A recommendation is weakened by a problem of statistical significance.

GC = gemcitabine plus cisplatin; G-CSF = granulocyte colony-stimulating factor; GR = grade of recommendation; MVAC = methotrexate, vinblastine, adriamycin plus cisplatin; HD MVAC = high-dose methotrexate, vinblastine, adriamycin plus cisplatin; LE = level of evidence; PS = performance status; PCG = paclitaxel, cisplatin, gemcitabine.

7.8.11 Biomarkers

Modest disease control rates, with sporadic marked responses, in some patients with urothelial BC have led to the investigation of biomarkers for assessment of postoperative prognosis and the potential value of perioperative chemotherapy, and as predictors of response to chemotherapy or its monitoring. Most of the biomarkers are associated with tumour angiogenesis. Small studies, usually retrospective, have investigated microvessel density, altered p53 tumour expression [474], serum vascular endothelial growth factor [475], urinary and tissue basic fibroblast growth factor [476], urinary (wild-type and mutant) and tissue fibroblast growth factor receptor-3 [477], and more recently, thrombospondin-1 [478], circulating tumour cells [479, 480], and multidrug resistance gene expression [481]. Although a few biomarkers have shown potential, as yet, there is insufficient evidence to support its routine clinical use (LE: 3).

7.8.11.1 Recommendation on the use of biomarkers

	GR
Currently, no biomarkers can be recommended in daily clinical practice because they have no impact on predicting outcome, treatment decisions, or monitoring therapy in muscle-invasive bladder cancer.	A*

*Upgraded following panel consensus.

GR = grade of recommendation.

Figure 7.2: Algorithm for the management of metastatic urothelial cancer

BSC = best supportive care; GC = gemcitabine plus cisplatin; GFR = glomerular filtration rate; MVAC = methotrexate, vinblastine, adriamycin plus cisplatin; HD MVAC = high-dose methotrexate, vinblastine, adriamycin plus cisplatin; PS = performance status; PCG = paclitaxel, cisplatin, gemcitabine.

7.9 Quality of life

7.9.1 Introduction

The evaluation of health-related quality of life (HRQoL) considers physical, psychological, emotional and social functioning.

Several questionnaires have been validated for assessing HRQoL in patients with BC, including FACT (Functional Assessment of Cancer Therapy)-G [482], EORTC QLQ-C30 [483], EORTC QLQ-BLM (muscle-invasive bladder cancer module) [484], and SF (Short Form)-36 [485, 486] and recently the BCI questionnaire specifically designed and validated for BC patients [487].

A psychometric test, such as the FACT-BL, should be used for recording BC morbidity. New intensive interviewing techniques have added valuable information to our knowledge of HRQoL, which greatly depends on patients' individual preferences in life [488].

Unfortunately, most retrospective studies do not evaluate the association between HRQoL and BC-specific issues after cystectomy, such as day-time and night-time incontinence or potency. Furthermore, important co-variables, such as a patient's age, mental status, coping ability and gender, have rarely been considered [489, 490]. It remains difficult to predict the impact of post-therapeutic symptoms because of individual differences in symptom tolerance.

7.9.2 **Choice of urinary diversion**

There is controversy about which type of urinary diversion is best for a patient's HRQoL [226]. Some studies have not demonstrated any difference in HRQoL [490-492]. Nevertheless, most patients stated that, given a choice, they would still opt for an orthotopic diversion rather than an ileal conduit [493]. Another study reported that, although urinary function is better in conduit patients, the urinary bother is the same in both diversion groups, resulting in the same HRQoL evaluation [494].

Due to improved surgical techniques in orthotopic bladder substitution, some recent studies are supportive of continent bladder substitutes [334, 484, 495-497]. Patients with an orthotopic substitution had significantly better physical function and a more active lifestyle compared to patients with an ileal conduit. It is important to note that HRQoL parameters are independent prognostic factors for OS [498]. Patients with a continent bladder-substitute generally scored more favourably than those with an incontinent diversion, as judged by body image, social activity and physical function [494, 495, 499].

7.9.3 **Non-curative or metastatic bladder cancer**

In non-curative or metastatic BC, HRQoL is reduced because of associated micturition problems, bleeding, pain and therefore disturbance of social and sexual life [500]. There is limited literature describing HRQoL in BC patients receiving palliative care [501], but there are reports of bladder-related symptoms relieved by palliative surgery [350], radiotherapy [502], and/or chemotherapy [503].

Alternative definitive treatments of MIBC, e.g. trimodality bladder-sparing procedures, have shown similar survival times compared to cystectomy. However, the impact on HRQoL has been controversial [123, 361, 503-507].

7.9.4 **Conclusions and recommendations for HRQoL**

Conclusions	LE
No randomised, prospective HRQoL study has evaluated the different forms of definitive treatment for MIBC.	2b
In most patient groups studied, the overall HRQoL after cystectomy remains good, irrespective of the type of urinary diversion used. The suggestion that continent diversions are associated with a higher HRQoL has not been sufficiently substantiated.	
Important determinants of (subjective) QoL are a patient's personality, coping style and social support.	

Recommendations	GR
The use of validated questionnaires is recommended to assess HRQoL in patients with MIBC.	B
Unless a patient's comorbidities, tumour variables and coping abilities present clear contraindications, a continent urinary diversion should also be offered.	C
Pre-operative patient information, patient selection, surgical techniques, and careful post-operative follow-up are the cornerstones for achieving good long-term results.	C
Patients should be encouraged to take active part in the decision-making process. Clear and exhaustive information on all potential benefits and side-effects should be provided, allowing them to make informed decisions.	C

HRQoL = health-related quality of life; MIBC = muscle-invasive bladder cancer.

8. FOLLOW-UP

8.1 Introduction

An appropriate schedule for disease monitoring should be based on:

- natural timing of recurrence;
- probability and site of recurrence;
- functional monitoring after urinary diversion;
- possible treatment of recurrence [508].

Nomograms on cancer-specific survival following radical cystectomy have been developed and externally validated. However, their wider use cannot be recommended prior to further data [509-511].

Surveillance protocols are commonly based on patterns of recurrence observed from retrospective series. Diagnosis of asymptomatic recurrence based on routine oncological follow-up and results from retrospective studies are controversial [512, 513]. Importantly, these retrospective studies use different follow-up regimens and imaging techniques that make final analysis and conclusive recommendations difficult. Prospective trials demonstrating the effectiveness of follow-up after RC and its impact on overall survival (OS) are lacking [514].

8.2 Site of recurrence

8.2.1 Local recurrence

Local recurrence takes place in soft tissues at the original surgical site or lymph nodes in the area of LND. Lymph node involvement above the aortic bifurcation can be considered metastatic recurrence [512].

Contemporary cystectomy has a 5-15% probability of pelvic recurrence. Most recurrence manifests during the first 24 months, often within 6-18 months after surgery. However, late recurrence can occur up to 5 years after cystectomy. Pathological stage and lymph node status are predictive for pelvic recurrence, as well as positive margins, extent of LND, and perioperative chemotherapy [515].

Patients have poor prognosis after pelvic recurrence. Even with treatment, the median survival ranges from 4 to 8 months following diagnosis. Definitive therapy can prolong survival, but mostly provides significant palliation of symptoms. Treatment includes systemic chemotherapy, local surgery, or radiotherapy [514].

8.2.2 Distant recurrence

Distant recurrence is seen in up to 50% of patients treated with cystectomy. Stage and nodal involvement are risk factors [516]. Systemic recurrence is more common in locally advanced disease (pT3/4), ranging from 32 to 62%, and in patients with lymph node involvement (range 52-70%) [517].

The most likely sites for distant recurrence are lymph nodes, lungs, liver and bone [518]. Nearly 90% of distant recurrence appears within the first 3 years after RC, mainly in the first 2 years, although late recurrence has been described after > 10 years. Median survival of patients with progressive disease treated with platinum-based chemotherapy is 9-26 months [519-521].

Despite periodic monitoring, > 50% of metastases are diagnosed after symptom appearance.

The value of monitoring in the diagnosis of asymptomatic metastases and its impact on survival is questionable. Some studies have demonstrated no impact on survival despite using routine monitoring, although others have suggested that diagnosis of asymptomatic metastases, especially in the lungs, improves survival [512, 513]. We must also consider the possibility of longer survival in patients with minimal metastatic disease undergoing multimodal treatment, including metastasectomy. There are reports of survival rates of 28-33% at 5 years in patients undergoing resection of metastases after objective response to chemotherapy [461, 468].

8.2.3 Post-cystectomy urothelial tumour recurrence

The incidence of new urethral tumours after RC is 1.5-6.0% in men, with a mean recurrence-free interval of 13.5-39.0 months and median survival of 28-38 months, of which > 50% die from systemic disease.

Secondary urethral tumours are likely to occur at 1-3 years after surgery. Prophylactic urethrectomy at cystectomy is no longer justified in most patients. Independent predictors for urethral recurrence are: cystectomy for NMIBC, prostate involvement, and history of recurrent NMIBC [514].

In women, the main risk factor is bladder neck disease [522]. Many studies have demonstrated that the risk of urethral recurrence after orthotopic diversion (0.9-4.0%) [523-526] is significantly less than after non-orthotopic diversion (6.4-11.1%) [523, 525].

There are limited data and agreement about urethral follow-up, with some recommending routine surveillance with urethral wash and urine cytology [526], and others doubting the need for routine urethral surveillance [524, 527-529]. Urethral washes and urine cytology do not appear to affect survival [527, 530, 531]. However, there is a significant survival advantage in men with urethral recurrence diagnosed asymptotically versus symptomatically, so follow-up of the male urethra is indicated in patients at risk of urethral recurrence [514].

Treatment is influenced by local stage and grade of urethral occurrence:

- in urethral CIS, BCG instillations have success rates of 83% [526];
- in invasive disease, urethrectomy should be performed if the urethra is the only site of disease;
- in distant disease, systemic chemotherapy is indicated [518].

Upper urinary urothelial carcinomas (UTUC) occur in 1.8-6.0% of cases and represent the most common sites of late recurrence (3 years disease-free survival following RC). Median OS is 10-55 months, and 60-67% of patients die of metastatic disease [514].

A recent meta-analysis found that 38% of UTUC recurrence was diagnosed by follow-up investigation, whereas in the remaining 62%, diagnosis was based on symptoms. When urine cytology was used in surveillance, the rate of primary detection was 7% and 29.6% with UUT imaging [532]. This meta-analysis concluded that patients with non-invasive cancer are twice as likely to have UTUC as patients with invasive disease. Multifocality increases the risk of recurrence by threefold, while positive ureteral or urethral margins increase the risk by sevenfold. Radical nephroureterectomy can prolong survival [533].

8.2.4 Conclusions and recommendations for specific recurrence sites

Site of recurrence	Conclusion	LE	Recommendation	GR
Local recurrence	Poor prognosis. Treatment should be individualised depending on the local extent of tumour.	2b	Radiotherapy, chemotherapy and possibly surgery are options for treatment, either alone or in combination.	C
Distant recurrence	Poor prognosis.	2b	Chemotherapy is the first option, and consider individualised cases for metastasectomy in the case of a unique metastasis site.	C
Upper urinary tract recurrence	Multifocal disease (NMIBC/ CIS or positive ureteral margins.		See EAU guidelines on Upper Urinary Tract Carcinomas [1].	
Secondary urethral tumour	Staging and treatment should be done as for primary urethral tumour.	3	Local conservative treatment is possible for non-invasive tumour.	C
			In isolated invasive disease, urethrectomy should be performed.	B
			Urethral washes and cytology are not recommended.	A

Although general recommendations are not advised based on high level of evidence, closer follow-up could be considered in patients with locally advanced disease or lymph node involvement. The suggested follow-up includes 4-monthly CT scans during the first year, 6-monthly until the 3rd year, and annual imaging thereafter.

In patients with multifocal disease, NMIBC with CIS or positive ureteral margins are at higher risk of developing UTUC which can develop late (> 3 years). In those cases, monitoring of the UUT is mandatory during follow-up. Computed tomography should be used to assess the UUT [532].

8.3 Follow-up of functional outcomes and complications

Apart from oncological surveillance, patients submitted for urinary diversion deserve functional follow-up. Complications related to urinary diversion are detected in 45% of patients during the first 5 years follow-up.

This rate increases over time, and exceeds 54% after 15 years follow-up. Therefore, long-term follow-up of functional outcomes is desirable [514] (LE: 3), and may stop after 15 years.

The functional complications are diverse and include: vitamin B12 deficiency, metabolic acidosis, worsening of renal function, urinary infections, urolithiasis, stenosis of uretero-intestinal anastomosis, stoma complications in patients with ileal conduit, neobladder continence problems, and emptying dysfunction [514].

1. INTRODUCTION

1.1 Aims and scope

The aim of these guidelines is to deliver current evidence-based information on the diagnosis and treatment of patients with primary urethral carcinoma (UC). When the first carcinoma in the urinary tract is detected in the urethra, this is defined as primary UC, in contrast to secondary UC, which presents as recurrent carcinoma in the urethra after prior diagnosis and treatment of carcinoma elsewhere in the urinary tract. Most often, secondary UC is reported after radical cystectomy for bladder cancer [1] (see Chapter 7.4 of the EAU Guidelines on Muscle-invasive and Metastatic Bladder Cancer [2] of the full text versions).

1.2 Panel composition

The EAU Guidelines Panel on Muscle-invasive and Metastatic Bladder Cancer is responsible for this publication. This is an international multidisciplinary group of clinicians, including a pathologist, an oncologist and a radiologist. Members of this panel have been selected based on their expertise to represent the professionals treating patients suspected of harbouring urethral carcinoma.

All experts involved in the production of this document have submitted potential conflict of interest statements.

1.3 Publication history and summary of changes

The Primary Urethral Carcinoma Guidelines were first published in 2013 [3]. This is the first update of this document.

1.3.1 Summary of changes

The literature for the complete document has been assessed and updated, whenever relevant.

Key changes for the 2015 publication:

- Evaluation of recent data on prognostic factors on oncologic outcomes in primary UC;
- Evaluation of recent data on the degree of concordance between clinical and pathologic staging;
- Evaluation of recent data on distal urethrectomy in men;
- Evaluation of recent data on the prognostic effect of multimodal treatment in advanced primary UC.

Conclusions and recommendations have been rephrased and added throughout the document, not resulting in a change in the level of evidence (LE) or grade of recommendation (GR). These changes can be found in the following sections:

6.2 Predictors of survival in primary urethral carcinoma

Conclusion	LE
Risk factors for survival in primary UC are: age, race, tumour stage and grade, nodal stage, presence of distant metastasis, histological type, tumour size, tumour location, concomitant bladder cancer and type and modality of treatment.	3

7.1 Treatment of localised primary urethral carcinoma in males

Recommendation	LE	GR
In localised anterior urethral tumours, distal urethrectomy presents an alternative to achieve negative surgical margins and should be offered as an alternative to penile amputation.	3	B

7.2.2 Radiotherapy

Recommendations	LE	GR
In women, local radiotherapy is an alternative to urethral surgery for localised urethral tumours but local toxicity needs to be considered.	3	C

7.3.2 Preoperative chemoradiotherapy in locally advanced squamous cell carcinoma of the urethra

Conclusions	LE
In locally advanced UC, cisplatin-based chemotherapy with curative intent prior to surgery improves survival compared to chemotherapy alone or surgery followed by chemotherapy.	4
In locally advanced squamous cell carcinoma (SCC) of the urethra, the prognostic role and timing of surgery after completion of chemoradiotherapy is unclear.	4

Recommendations	LE	GR
Chemotherapeutic regimens with curative intent prior to surgery should be cisplatinum-based.	4	C
In locally advanced SCC of the urethra, combination of curative radiotherapy with radiosensitising chemotherapy is an option for genital preservation.	4	C

SCC = squamous cell carcinoma; UC = urethral carcinoma.

2. METHODS

2.1 Literature identification

An updated systematic literature search was performed to identify studies reporting data on urethral malignancies since the last search on 15th October 2012 until 15th August 2014. Medline was searched using the controlled vocabulary of the Medical Subject Headings (MeSH) database, along with a free-text protocol, using one or several combinations of the following terms: *adenocarcinoma, adjuvant treatment, anterior, chemotherapy, distal urethral carcinoma, lower, neoadjuvant, partial, penectomy, penile-preserving surgery, posterior, primary, proximal urethral carcinoma, radiotherapy, recurrence, risk factors, squamous cell carcinoma, survival, transitional cell carcinoma, urethra, urethrectomy, urethral cancer, urinary tract, and urothelial carcinoma*. No randomised controlled trials were identified and articles were selected based on study design, treatment modality and long-term outcomes. Older studies (> 10 years) were considered if they contained historically relevant data or in the absence of newer data.

In this 2015 EAU Guidelines compilation, all standard information on levels of evidence (LE) and grading of recommendations (GR) has been taken out of the individual guidelines topics for the sake of brevity. This information is included in the introductory section of this print.

2.2 Review

This document was subjected to double-blind peer review prior to publication.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Primary UC is considered a rare cancer, accounting for < 1% of all malignancies [4] (ICD-O3 topography code: C68.0 [5]).

In early 2008, the prevalence of UC in the 27 EU countries was 4,292 cases with an estimated annual incidence of 655 new cases [6]. The age-standardised ratio was 1.1 per million inhabitants (1.6/million in men and 0.6/million in women; with a male to female ratio of 2.9) [6]. There were differences between European regions; potentially caused by registration or classification [6]. Likewise, in an analysis of the Surveillance, Epidemiology and End Results (SEER) database, the incidence of primary UC peaked in the ≥ 75 years age group (7.6/million). The age-standardised rate was 4.3/million in men and 1.5/million in women, and was almost negligible in those aged < 55 years (0.2/million) [7].

3.2 Aetiology

For male primary UC, various predisposing factors have been reported, including urethral strictures [8, 9], chronic irritation after intermittent catheterisation/urethroplasty [10-12], external beam irradiation therapy [13], radioactive seed implantation [14], and chronic urethral inflammation/urethritis following sexually transmitted diseases (i.e. condylomata associated with human papilloma virus 16) [15, 16]. In female UC, urethral diverticula [17-19] and recurrent urinary tract infections [20] have been associated with primary urethral carcinoma. Clear cell adenocarcinoma may also have a congenital origin [21, 22].

3.3 Histopathology

Both the Surveillance of Rare Cancers in Europe (RARECARE) project and SEER database have reported that urothelial carcinoma of the urethra is the predominant histological type of primary urethral cancer (54-65%), followed by squamous cell carcinoma (SCC; 16-22%) and adenocarcinoma (AC; 10-16%) [6, 7]. A recent SEER

analysis of 2,065 men with primary urethral cancer (mean age: 73 years) found that urothelial carcinoma (78%) was most common, and SCC (12%) and AC (5%) were significantly less frequent [23]. In women, a recent report of the Dutch National Cancer Registry on primary urethral cancer reported that urothelial carcinoma occurred in 45% of cases, followed by AC in 29%, SCC in 19%, and other histological entities in 6% [24].

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Tumor, Node, Metastasis (TNM) staging system

In men and women, UC is classified according to the 7th edition of the TNM classification [5] (Table 4.1). It should be noted that there is a separate TNM staging system for prostatic UC [5]. Of note, for cancers occurring in urethral diverticulum stage, T2 is not applicable as urethral diverticula are lacking periurethral muscle [25].

Table 4.1: TNM classification (7th edition) for UC [5]. Primary tumour stage is separated into UC and UC of the prostate

T - Primary tumour (men and women)	
Tx	Primary tumour cannot be assessed
Tis	Carcinoma <i>in situ</i>
T0	No evidence of primary tumour
Ta	Non-invasive papillary carcinoma
T1	Tumour invades subepithelial connective tissue
T2	Tumour invades any of the following structures: corpus spongiosum, prostate, peri-urethral muscle
T3	Tumour invades any of the following structures: corpus cavernosum, invasion beyond prostatic capsule, anterior vaginal wall, bladder neck
T4	Tumour invades other adjacent organs
Primary tumour in prostatic urethra	
Tx	Primary tumour cannot be assessed
Tis pu	Carcinoma <i>in situ</i> in the prostatic urethra
Tis pd	Carcinoma <i>in situ</i> in the prostatic ducts
T0	No evidence of primary tumour
T1	Tumour invades subepithelial connective tissue (only in case of concomitant prostatic urethral involvement)
T2	Tumour invades any of the following structures: corpus spongiosum, prostatic stroma, periurethral muscle
T3	Tumour invades any of the following structures: corpus cavernosum, beyond prostatic capsule, bladder neck
T4	Tumour invades other adjacent organs
N - Regional lymph nodes	
Nx	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastases
N1	Metastasis in a single lymph node ≤ 2 cm in greatest dimension
N2	Metastasis in a single lymph node > 2 cm in greatest dimension or in multiple nodes
M - Distant metastasis	
Mx	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis

4.2 Tumour grade

The former World Health Organization (WHO) grading system of 1973 which differentiated urothelial carcinomas into three different grades (G1-G3) has been replaced by the grading system of 2004 that differentiates urothelial UC into papillary urothelial neoplasm of low malignant potential (PUNLMP), low grade and high grade. Non-urothelial UC is graded by a trinomial system that differentiates between well-differentiated (G1), moderately differentiated (G2), and poorly differentiated tumours (G3). Table 4.2 lists the different grading systems according to the WHO 1973 and 2004 systems [26].

Table 4.2: Histopathological grading of urothelial and non-urothelial primary UC [26]

PUNLMP	Papillary urothelial neoplasm of low malignant potential
Low grade	Well differentiated
High grade	Poorly differentiated

Non-urothelial UC	
Gx	Tumour grade not assessable
G1	Well differentiated
G2	Moderately differentiated
G3	Poorly differentiated

Recommendation	LE	GR
Pathological staging and grading of primary UC should follow the 2009 TNM classification and WHO 2004 grading system.	3	B

TNM = Tumour, Node, Metastasis; WHO = World Health Organization.

5. DIAGNOSTIC EVALUATION AND STAGING

5.1 History

When becoming clinically apparent, most patients (45-57%) with primary UC present with symptoms associated with locally advanced disease (T3/T4) [25, 27]. At initial presentation visible haematuria or bloody urethral discharge is reported in up to 62% of the cases. Further symptoms of locally advanced disease include an extraurethral mass (52%), bladder outlet obstruction (48%), pelvic pain (33%), urethrocutaneous fistula (10%), abscess formation (5%) or dyspareunia [27].

5.2 Clinical examination

In men, physical examination should comprise palpation of the external genitalia for suspicious indurations or masses and digital rectal examination [28]. In women, further pelvic examination with careful inspection and palpation of the urethra should be performed, especially in those with primary onset of irritative or obstructive voiding. In addition, bimanual examination, when necessary under general anaesthesia, should be performed for local clinical staging and to exclude the presence of colorectal or gynaecological malignancies. Bilateral inguinal palpation should be conducted to assess the presence of enlarged lymph nodes, describing location, size and mobility [29].

5.3 Urinary cytology

The role of urinary cytology in primary UC is limited, and its sensitivity ranges between 55% and 59% [30]. Detection rate depends on the underlying histological entity. In male patients, the sensitivity for urothelial carcinoma and SCC was reported to be 80% and 50%, respectively, whereas in female patients sensitivity was found to be 77% for SCC and 50% for urothelial carcinoma.

5.4 Diagnostic urethrocystoscopy and biopsy

Diagnostic urethrocystoscopy and biopsy enables primary assessment of a urethral tumour in terms of tumour extent, location and underlying histology [28]. To enable accurate pathological assessment of surgical margins, biopsy sites (proximal/distal end) should be marked and sent together with clinical information to the pathologist.

Careful cystoscopic examination is necessary to exclude the presence of concomitant bladder tumours [3, 31]. A cold-cup biopsy enables accurate tissue retrieval for histological analysis and avoids artificial tissue damage. In patients with larger lesions, transurethral resection (optionally in men under penile blood arrest using a tourniquet) can be performed for histological diagnosis. In patients with suspected urothelial carcinoma of the prostatic urethra or ducts, resectoscope loop biopsy of the prostatic urethra (at 5 and 7 o'clock positions from the bladder neck and distally around the area of the verumontanum) can contribute to an improved detection rate [32].

5.5 Radiological imaging

Radiological imaging of urethral cancer aims to assess local tumour extent and to detect lymphatic and distant metastatic spread. For local staging, there is increasing evidence that magnetic resonance imaging (MRI) is an accurate tool for monitoring tumour response to neoadjuvant chemoradiotherapy and evaluating the extent of local disease prior to exenterative surgery [33]. Imaging for regional lymph node metastases should concentrate on inguinal and pelvic lymph nodes, using either MRI or CT. Distant staging should concentrate on chest and liver, with CT of the thorax and abdomen in all patients with invasive disease (\geq cT1N0M0 [33-37]. If imaging of the remainder of the urothelium is required, then CT should include CT urography with an excretory phase [38].

5.6 Regional lymph nodes

Enlarged lymph nodes in urethral cancer often represent metastatic disease [39, 40]. In men, lymphatics from the anterior urethra drain into the superficial- and deep inguinal lymph nodes and subsequently to the pelvic (external, obturator and internal iliac) lymph nodes. Conversely, lymphatic vessels of the posterior urethra drain into the pelvic lymph nodes. In women, the lymph of the proximal third drains into the pelvic lymph node chains, whereas the distal two-thirds initially drain into the superficial- and deep inguinal nodes [41, 42].

Nodal control in urethral cancer can be achieved either by regional lymph node dissection [28], radiotherapy [43] or chemotherapy [39]. Currently, there is still no clear evidence to support prophylactic bilateral inguinal and/or pelvic lymphadenectomy in all patients with urethral cancer. However, in patients with clinically enlarged inguinal/pelvic lymph nodes or invasive tumours, regional lymphadenectomy should be considered for initial treatment because cure might still be achievable with limited disease [28].

Conclusion	LE
Patients with clinically enlarged inguinal or pelvic lymph nodes often exhibit pathological lymph node metastasis.	3

Recommendations	LE	GR
Diagnosis includes urethrocystoscopy with biopsy and urinary cytology.	3	B
CT of the thorax and abdomen should be used to assess distant metastases.	3	B
Pelvic MRI is the preferred method to assess local extent of urethral tumour.	3	B

CT = computed tomography; MRI = magnetic resonance imaging.

6. PROGNOSIS

6.1 Long-term survival after primary urethral carcinoma

According to the RARECARE project, the mean 1- and 5-year overall survival in patients with UC in Europe is 71% and 54%, respectively [6]. With longer follow-up, a SEER analysis of 1,615 cases reported median 5- and 10-year overall survival rates of 46% and 29%, respectively. Cancer-specific survival at 5 and 10 years was 68% and 60%, respectively [7].

6.2 Predictors of survival in primary urethral carcinoma

In Europe, mean 5-year overall survival does not substantially differ between the sexes [6]. Predictors of decreased survival in patients with primary UC are:

- advanced age (\geq 65 years) and black race [6, 44];
- stage, grade, nodal involvement [40] and metastasis [23];
- tumour size and proximal tumour location [23];
- extent of surgical treatment and treatment modality [23, 44];
- underlying histology [6, 24, 44];
- presence of concomitant bladder cancer [31].

Some limitations have to be taken into account in the interpretation of these results. In the Dutch study, the numbers were low ($n = 91$) [25]. In the large SEER database ($n = 2,046$), therapy is not well specified in relation to survival [24]. Finally, in contrast to the RARECARE project [6], the opposite findings were reported in the SEER database in relation to the role of histology on survival in male patients [44].

Conclusion	LE
Risk factors for survival in primary UC are: age, race, tumour stage and grade, nodal stage, presence of distant metastasis, histological type, tumour size, tumour location, concomitant bladder cancer and type and modality of treatment.	3

7. DISEASE MANAGEMENT

7.1 Treatment of localised primary urethral carcinoma in males

Previously, treatment of male anterior urethral cancer has followed the procedure for penile cancer, with aggressive surgical excision of the primary lesion with a wide safety margin [28]. Distal urethral tumours exhibit significantly improved survival rates compared with proximal tumours [45]. Therefore, optimising treatment of distal urethral cancer has become the focus of clinicians to improve functional outcome and quality of life, while preserving oncological safety. A retrospective series found no evidence of local recurrence, even with < 5 mm resection margins (median follow-up: 17-37 months), in men with pT1-3N0-2 anterior UC treated with well-defined penis-preserving surgery and additional iliac/inguinal lymphadenectomy for clinically suspected lymph node disease [46]. This suggests that prognosis is mainly determined by nodal stage. Similar results for the feasibility of penile-preserving surgery have been also reported in a recent series [47].

Recommendation	LE	GR
In localised anterior urethral tumours, distal urethrectomy presents an alternative to achieve negative surgical margins and should be offered as an alternative to penile amputation.	3	B

7.2 Treatment of localised urethral carcinoma in females

7.2.1 Urethrectomy and urethra-sparing surgery

In women with localised urethral cancer, to provide the highest chance of local cure, primary radical urethrectomy should remove all the periurethral tissue from the bulbocavernosus muscle bilaterally and distally, with a cylinder of all adjacent soft tissue up to the pubic symphysis and bladder neck. Bladder neck closure and via an appendico-vesicostomy for primary anterior urethral lesions has been shown to provide satisfactory functional results in women [28].

Recent series have reported outcomes in women with mainly anterior urethral cancer undergoing primary treatment with urethra-sparing surgery or radiotherapy, compared to primary urethrectomy, with the aim of maintaining integrity and function of the lower urinary tract [48-50]. In long-term series with a median follow-up of 153-175 months, local recurrence rates in women undergoing partial urethrectomy with intraoperative frozen section analysis were 22-60%, and distal sleeve resection of > 2 cm resulted in secondary urinary incontinence in 42% of patients who required additional reconstructive surgery [48, 49]. Ablative surgical techniques, i.e., transurethral resection (TUR) or laser, used for small distal urethral cancer, have also resulted in a considerable local failure rate of 16%, with a cancer-specific survival rate of 50%. This emphasises the critical role of local tumour control in women with distal urethral cancer to prevent local and systemic progression [48].

7.2.2 Radiotherapy

In women, radiotherapy was investigated in several older long-term series with a medium follow-up of 91-105 months [43, 46]. With a median cumulative dose of 65 Gy (range: 40-106 Gy), the 5-year local control rate was 64% and 7-year cancer-specific survival was 49% [43]. Most local failures (95%) occurred within the first two years after primary treatment [46]. The extent of urethral tumour involvement was found to be the only parameter independently associated with local tumour control but the type of radiotherapy (external beam radiotherapy vs. interstitial brachytherapy) was not [43]. In one study, the addition of brachytherapy to external beam radiotherapy reduced the risk of local recurrence by a factor of 4.2 [51]. Of note, pelvic toxicity in those achieving local control was considerable (49%), including urethral stenosis, fistula, necrosis, and cystitis and/or haemorrhage, with 30% of the reported complications graded as severe [43].

Recommendations	LE	GR
In women with anterior urethral tumours, urethra-sparing surgery is an alternative to primary urethrectomy if negative surgical margins can be achieved intraoperatively.	3	B
In women, local radiotherapy is an alternative to urethral surgery for localised urethral tumours but local toxicity needs to be considered.	3	C

7.3 Multimodal treatment in advanced urethral carcinoma in both genders

7.3.1 Preoperative platinum-based chemotherapy

Recent retrospective studies have reported that modern platinum-based polychemotherapeutic regimens are effective in advanced primary urethral cancer, providing prolonged survival even in lymph-node-positive disease. Moreover, they have emphasised the critical role of surgery after chemotherapy for achieving long-term survival in patients with locally advanced urethral cancer.

In a series of 39 patients treated with perioperative platinum-based chemotherapy for advanced primary UC, preoperative chemotherapy was found to be associated with improved progression-free and overall survival compared to surgery followed by adjuvant chemotherapy [52]. Another series reported outcomes in 44 patients with advanced primary urethral cancer treated with specific cisplatin-based polychemotherapeutic regimens according to the underlying histology. The overall response rate for the various regimens was 72% and the median overall survival 32 months. Patients who underwent surgery after chemotherapy had significantly improved overall survival compared with those who were managed with chemotherapy alone [39].

7.3.2 Preoperative chemoradiotherapy in locally advanced squamous cell carcinoma of the urethra

The clinical feasibility of preoperative local radiotherapy with concurrent radiosensitising chemotherapy as an alternative to surgery in locally advanced SCC has been reported in several recent series. This approach offers a potential for genital preservation [52-57]. The largest and recently updated series reported outcomes in 25 patients with primary locally advanced SCC of the urethra treated with two cycles of 5-fluorouracil and mitomycin C with concurrent external beam radiotherapy. A complete response to primary chemoradiotherapy was observed in ~80%. The 5-year overall- and disease-specific survival was 52% and 68%, respectively. In this updated series, salvage surgery initiated only in non-responders or in case of local failure was not reported to be associated with improved survival [53].

Conclusions	LE
In locally advanced UC, cisplatin-based chemotherapy with curative intent prior to surgery improves survival compared to chemotherapy alone or surgery followed by chemotherapy.	4
In locally advanced SCC of the urethra, the prognostic role and timing of surgery after completion of chemoradiotherapy is unclear.	4

Recommendations	LE	GR
Patients with locally advanced UC should be discussed within a multidisciplinary team of urologists, radio-oncologists and oncologists.	4	A
Chemotherapeutic regimens with curative intent prior to surgery should be cisplatin-based.	4	C
In locally advanced SCC of the urethra, combination of curative radiotherapy with radiosensitising chemotherapy is an option for genital preservation.	4	C

SCC = squamous cell carcinoma; UC = urothelial carcinoma.

7.4 Treatment of urothelial carcinoma of the prostate

Local conservative treatment with extensive TUR and subsequent Bacille-Calmette-Guérin (BCG) instillation is effective in patients with Ta or Tis prostatic UC [58, 59]. Likewise, patients undergoing TUR of the prostate prior to BCG experience improved complete response rates compared with those who do not (95% vs. 66%) [60]. Risk of understaging local extension of prostatic urethral cancer at TUR is increased, especially in patients with ductal or stromal involvement [61]. In smaller series, response rates to BCG in patients with prostatic duct involvement have been reported to vary between 57 and 75% [58, 62]. Some earlier series have reported superior oncological results for the initial use of radical cystoprostatectomy as a primary treatment option in patients with ductal involvement [63, 64]. In 24 patients with prostatic stromal invasion treated with radical cystoprostatectomy, a lymph node mapping study found that 12 patients had positive lymph nodes, with an increased proportion located above the iliac bifurcation [65].

Recommendations	LE	GR
Patients with non-invasive UC or carcinoma <i>in situ</i> of the prostatic urethra and prostatic ducts can be treated with a urethra-sparing approach with TUR and BCG.	3	C
In patients with non-invasive UC or carcinoma <i>in situ</i> , prior TUR of the prostate should be performed to improve response to BCG.	3	C
Cystoprostatectomy with extended pelvic lymphadenectomy should be reserved for patients not responding to BCG or as primary treatment option in patients with extensive ductal or stromal involvement.	3	C

BCG = *Bacille-Calmette-Guérin*; TUR = *transurethral resection*; UC = *urothelial carcinoma*.

8. FOLLOW-UP

COMMENTARY: Given the low incidence of primary urethral cancer, defined follow-up has not been investigated systematically so far. Therefore, it seems reasonable to tailor surveillance regimens according to the patients' individual risk factors (Chapter 6.2). In patients undergoing urethra-sparing surgery, it seems prudent to advocate a more extensive follow-up with urinary cytology, urethrocytscopy and cross-sectional imaging despite the lack of specific data.

10. CONFLICT OF INTEREST

All members of the Muscle-invasive and Metastatic Bladder Cancer guidelines working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: <http://www.uroweb.org/guidelines/>. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

1. INTRODUCTION

1.1 Aims and scope

The European Association of Urology (EAU) Prostate Cancer Guidelines Panel have prepared this guidelines document to assist medical professionals assess the evidence-based management of prostate cancer (PCa).

1.2 Panel composition

The Prostate Cancer Guidelines Panel consists of an international multidisciplinary group of urologists, radiation oncologists, medical oncologists, a radiologist, a pathologist and a patient stakeholder organisation representative.

1.2.1 Acknowledgement

The EAU Prostate Cancer Guidelines Panel are most grateful for the support and considerable expertise provided by Prof. Dr. J-P. Droz, Emeritus Professor of Medical Oncology (Lyon, France) for the topic of 'Management of prostate cancer in senior adults'. As a leading expert in this field, and prominent member of the International Society of Geriatric Oncology, his contribution has been invaluable.

1.2.2 Potential conflict of interest

All experts involved in the production of this document have submitted potential conflict of interest statements.

1.3 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available [1, 2] as are a number of translations of all versions of the Prostate Cancer guidelines. All documents can be viewed, free access, through the EAU website Uroweb: <http://www.uroweb.org/guidelines/online-guidelines/>.

1.4 Publication history and summary of changes

1.4.1 Publication history

The first EAU Guidelines on Prostate Cancer were published in 2001. This current 2015 document presents a full update of the 2014 full text document. The literature for the complete document has been assessed and updated, whenever relevant.

1.4.2 Summary of changes

Key changes for this 2015 print:

Table 4.1.2: EAU risk groups for biochemical recurrence of localised and locally advanced prostate cancer

	Low-risk	Intermediate-risk	High-risk	
Definition	PSA < 10 ng / mL and GS < 7 and cT1-2a	PSA 10-20 ng /mL or GS 7 or cT2b	PSA > 20 ng / mL or GS > 7 or cT2c	any PSA any GS cT3-4 or cN+
	Localised			Locally advanced

Conclusions and recommendations have been rephrased and added to throughout the current document. Changed or new conclusions and recommendations can be found in sections:

5.2.4.3 Guidelines for imaging

	LE	GR
When clinical suspicion of PCa persists in spite of negative biopsies, MRI-targeted biopsies are recommended.	2b	B

Table 5.2.4: Recommended terminology for reporting prostate biopsies [3]

• Benign/negative for malignancy. If appropriate, include a description.
• Active inflammation.
• Granulomatous inflammation.
• High-grade PIN.
• High-grade PIN with atypical glands, suspicious for adenocarcinoma (PINATYP).
• Focus of atypical glands/lesion suspicious for adenocarcinoma/atypical small acinar proliferation, suspicious for cancer.
• Adenocarcinoma.

5.2.7 Guidelines for the clinical diagnosis of prostate cancer

	LE	GR
Transurethral resection of the prostate should not be used as a tool for cancer detection.	2a	A

5.3.4 Guidelines for staging of prostate cancer

Any risk group staging	LE	GR
Additional imaging is required only if it changes patient management.	2a	A*
For local staging, CT and TRUS should not be used.	3	A
For up-front staging, PET-scanning should not be used.	2a	A

Low-risk localised PCa	LE	GR
No additional imaging is recommended for staging purposes.	2a	A

Intermediate-risk PCa	LE	GR
In predominantly Gleason pattern 4, bone scan and cross-sectional imaging is required.	2a	A*

High-risk localised PCa/ High-risk locally advanced PCa	LE	GR
Prostate mpMRI should be used for local staging.	2b	A
CT/MRI and bone-scan should be used in staging.	2b	A
For up-front staging, PET-scanning should not be used.	2a	A

7.1.5 Guidelines for active surveillance and watchful waiting

Recommendations - active surveillance	LE	GR
Patients who are suitable for surgery and radiotherapy must have these options discussed with them.	4	A*

7.2.11 **Guidelines for radical prostatectomy**

	LE	GR
Patients who are suitable for AS and radiotherapy must have these options discussed with them.	4	A*
In patients with low- and intermediate-risk PCa and a life expectancy > 10 years, RP should be offered.	1b	A
Nerve-sparing surgery may be attempted in pre-operatively potent patients with low risk for extracapsular disease (T1c, GS < 7 and PSA < 10 ng/mL, or refer to Partin tables/nomograms).	2b	B
Multiparametric MRI may help in deciding when to perform nerve-sparing procedures in intermediate- and high-risk disease.	2b	B
In patients with high-risk localised PCa and a life expectancy of > 10 yr, RP should be offered in a multimodality setting.	2a	A
In selected patients with locally advanced (cT3a) PCa, and a life expectancy > 10 yr, RP may be offered in a multimodality setting.	2b	B
In highly selected patients with locally advanced PCa (cT3b-T4 N0 or any T N1), RP may be offered in a multimodality setting.	3	C
NHT before RP is not recommended.	1a	A
Adjuvant HT for pN0 is not recommended.	1a	A
Adjuvant ADT is the standard of care for node-positive (pN+) patients.	1b	A

7.3.10 **Conclusion and Guidelines for definitive radiotherapy**

Statement	LE
The highest effect of adjuvant radiotherapy is seen in patients with pT3R1 PCa.	1a

Recommendations	LE	GR
Patients who are suitable for AS and surgery must have these options discussed with them.	4	A
EBRT should be offered in all risk groups of non-metastatic PCa.	2a	A
In low-risk PCa, the total dose should be 74 to 78 Gy.	1a	A
In patients with low-risk PCa, without a previous TURP and with a good IPSS and a prostate volume < 50 mL, LDR brachytherapy is a treatment option.	2a	A
In intermediate-risk PCa, a total dose should be 76-78 Gy, in combination with short-term ADT (4-6 mo).	1b	A
In patients with high-risk localised PCa, a total dose of 76-78 Gy in combination with long-term ADT (2-3 yr) is recommended.	1b	A
In patients with locally advanced cN0 PCa, radiotherapy must be given in combination with long-term ADT (2-3 yr).	1a	A
IMRT is the recommended modality for definitive treatment of PCa by EBRT.	2a	A
In patients with cN+ PCa, pelvic external irradiation can be given in combination with immediate long-term ADT.	2b	B
In patients with pT3,N0M0 PCa and an undetectable PSA following RP, adjuvant external beam irradiation should be discussed as an option because it improves at least biochemical-free survival.	1a	A
Patients with pT3,N0M0 PCa and an undetectable PSA following RP should be informed about salvage irradiation as an alternative to adjuvant irradiation when PSA increases (See Section 6.10.5.1).	2b	A

Primary treatment of prostate cancer			GR
General comments	Patients suitable for several treatment modalities (active surveillance, surgery, radiotherapy) must have these options discussed with them.		A*
	In patients who are surgical candidates for radical prostatectomy, all approaches (i.e. open, laparoscopic or robotic) are acceptable as no single approach has shown clear superiority in terms of functional or oncological results.		A
	EBRT should be offered in all risk groups of non-metastatic PCa.		A
	IMRT is the recommended modality for definitive treatment of PCa by EBRT.		A
	Treatment	Comment	
Low risk PCa	Watchful waiting	Watchful waiting may be offered to patients not eligible for local curative treatment and those with a short life expectancy.	A
		During watchful waiting, the decision to start non-curative treatment should be based on symptoms and disease progression.	B
	Active surveillance	Active surveillance is an option in patients with the lowest risk of cancer progression: > 10 years life expectancy, cT1/2, PSA ≤ 10 ng/mL, biopsy Gleason score ≤ 6, ≤ 2 positive biopsies, minimal biopsy core involvement (≤ 50% cancer per biopsy).	A
		Follow-up should be based on DRE, PSA and repeat biopsies. The optimal follow-up interval is still unclear.	A
	Radical prostatectomy	In patients with a life expectancy > 10 years, RP should be offered.	A
		Nerve-sparing surgery may be attempted in pre-operatively potent patients with low risk for extracapsular disease (T1c, GS < 7 and PSA < 10 ng/mL, or refer to Partin tables/nomograms).	B
		LND is not indicated in low-risk PCa.	A
	Radiotherapy	In low-risk PCa the total dose should be 74 to 78 Gy.	A
		In patients with low-risk PCa, without a previous TURP and with a good IPSS and a prostate volume < 50 mL, LDR brachytherapy is a treatment option.	A
	Cryotherapy, HIFU	In patients who are unfit for surgery or radiotherapy, cryotherapy or HIFU might be an alternative treatment for PCa. The lack of long-term efficacy compared to standard modality should be discussed with patients.	C
	Focal treatment	Focal therapy of PCa is still in its infancy and cannot be recommended as a therapeutic alternative outside clinical trials.	A
	Androgen suppression	Unsuitable.	A
Intermediate risk PCa	Watchful waiting	Watchful waiting may be offered to patients not eligible for local curative treatment and those with a short life expectancy.	A
	Active surveillance	Not an option.	A
	Radical prostatectomy	In patients with a life expectancy > 10 years, RP should be offered.	A
		Nerve-sparing surgery may be attempted in pre-operatively potent patients with low risk for extracapsular disease (T1c, GS < 7 and PSA < 10 ng/mL, or refer to Partin tables/nomograms).	B

		Multiparametric MRI may help in deciding when to perform nerve-sparing procedures in intermediate- and high-risk disease.	B
		eLND should be performed if the estimated risk for positive lymph nodes exceeds 5%.	B
		Limited LND should not be performed.	A
		In patients with pT3,N0M0 PCa and an undetectable PSA following RP, adjuvant external beam irradiation should be discussed as an option because it improves at least biochemical-free survival.	A
		Patients with pT3,N0M0 PCa and an undetectable PSA following RP should be informed about salvage irradiation as an alternative to adjuvant irradiation when PSA increases.	A
		Adjuvant HT for pN0 is not recommended.	
	Radiotherapy	In intermediate-risk PCa, the total dose should be 76-78 Gy, in combination with short-term ADT (4-6 mo).	A
	Androgen suppression monotherapy	No place in asymptomatic patients.	A
High risk PCa	Watchful waiting	High risk localised: Watchful waiting may be offered to patients not eligible for local curative treatment and those with a short life expectancy.	
		High risk locally advanced: In M0 patients unwilling or unable to receive any form of local treatment, a deferred treatment policy using ADT as monotherapy is feasible in asymptomatic patients with a PSA-DT > 12 months and a PSA < 50 ng/mL and non-poorly differentiated tumour.	A
	Active surveillance	Not appropriate.	A
	Radical prostatectomy	NHT before RP is not recommended.	A
		eLND should be performed in high-risk PCa.	A
		Limited LND should not be performed.	A
		High risk localised: In patients with high-risk localised PCa and a life expectancy of > 10 yr, RP should be offered in a multimodality setting.	B
		Nerve-sparing surgery may be attempted in pre-operatively potent patients with low risk for extracapsular disease (refer to Partin tables/nomograms).	B
		Multiparametric MRI may help in deciding when to perform nerve-sparing procedures in intermediate- and high-risk disease.	B
		High risk locally advanced: In highly selected patients with locally advanced PCa (cT3b-T4 N0 or any T N1), RP may be offered in a multimodality setting.	C
		In patients with pT3,N0M0 PCa and an undetectable PSA following RP, adjuvant external beam irradiation should be discussed as an option because it improves at least biochemical-free survival.	A
		Patients with pT3,N0M0 PCa and an undetectable PSA following RP should be informed about salvage irradiation as an alternative to adjuvant irradiation when PSA increases.	A

	Radiotherapy	In patients with high-risk localised PCa, the total dose is 76-78 Gy in combination with long-term ADT (2-3 yr is recommended).	A
		In patients with locally advanced cN0 PCa, radiotherapy must be given in combination with long-term ADT (2-3 yr is recommended).	A
	Androgen suppression monotherapy	Reserved for those unwilling or unable to receive any form of local treatment and either symptomatic or asymptomatic with a PSA-DT < 12 months and a PSA > 50 ng/mL and a poorly differentiated tumour.	A
N1 patients			
cN1		In patients with cN+ PCa, pelvic external irradiation can be given in combination with immediate long-term ADT.	B
pN1 after eLND		Adjuvant ADT is the standard of care for node-positive (pN+) patients.	A
		Adjuvant ADT with additional radiotherapy may have a role.	B
		Expectant management is optional when the patient has undergone eLND and ≤ 2 nodes show microscopic involvement and a PSA < 0.1 ng/mL and absence of extranodal extension.	B
Metastatic PCa	Watchful waiting	In M1 asymptomatic patients, deferred castration should be discussed with a well-informed patient.	B
	Active surveillance	Unsuitable.	A
	Radical prostatectomy	Unsuitable outside clinical trial.	A
	Radiotherapy to the prostate	Unsuitable outside clinical trial.	A
	Androgen suppression	Surgical- or medical castration (LHRH agonist or antagonist).	A
		No recommendation can be made to define the best population for combining castration with upfront Docetaxel.	A
		Castration combined with local treatment / other new hormonal treatments (abiraterone acetate or Enzalutamide) should not be used outside clinical trials.	A
		In M1 asymptomatic patients, immediate castration should be offered to defer progression to a symptomatic stage and prevent serious disease progression-related complications.	A
		In M1 symptomatic patients, immediate castration should be offered to palliate symptoms and reduce the risk for potentially catastrophic sequelae of advanced disease (spinal cord compression, pathological fractures, ureteral obstruction, extraskeletal metastasis).	A
		In M1 patients, short-term administration of anti-androgens is recommended to reduce the risk of the 'flare-up' phenomenon in patients with advanced metastatic disease who are to receive an LHRH agonist.	A
		In M1 patients short-term administration of anti-androgens should be given for some weeks only (starting treatment on the same day as an LHRH analogue is started or for up to 7 days before the first LHRH analogue injection).	A
		In M1 patients, administration of anti-androgens as monotherapy should not be considered.	A
		In asymptomatic M1 patients, intermittent treatment can be offered to highly motivated men, with a major PSA response after the induction period.	B

	Based on the schedules in use in clinical trials, treatment is stopped when the PSA is < 4 ng/mL after 6 to 7 months of treatment. Treatment is resumed when the PSA is > 10-20 ng/mL.	C
	Combined treatment with LHRH agonists and NSAA is recommended.	A
	Antagonists might be an option.	B
Castrate resistant status	Patients should not be started on second-line therapy unless their testosterone serum levels are < 50 ng/dL.	A
	There is no evidence for treatment of non-metastatic CRPC outside a clinical trial.	A
	Patients with mCRPC should be counseled, managed and treated by a multidisciplinary team.	A
	Men treated with maximal androgen blockade should stop the anti-androgen therapy once PSA progression is documented. <i>Comment: Four to six weeks after discontinuation of flutamide or bicalutamide, an eventual anti-androgen withdrawal effect will be apparent.</i>	A
	No clear-cut recommendation can be made for the most effective drug for secondary treatment (i.e. hormone therapy or chemotherapy) as no clear predictive factors exist.	A
	Salvage hormonal treatment using abiraterone acetate is a valid option.	A
	Salvage hormonal treatment using enzalutamide is a valid option.	A
	In patients with metastatic CRPC who are candidates for salvage cytotoxic therapy, docetaxel at 75 mg/m ² every 3 weeks has shown a significant survival benefit.	A
	In patients with relapse following salvage docetaxel chemotherapy cabazitaxel, abiraterone acetate and enzalutamide are regarded as first-choice options for second-line treatment in mCRPC.	A
	In men with mCRPC with symptomatic bone metastases, who are ineligible for or progressing after docetaxel, treatment with Ra 223 (alpharadin) has shown a survival benefit.	A
	Bone protective agents may be offered to patients with skeletal metastases (denosumab being superior to zoledronic acid) to prevent osseous complications. However, the benefits must be balanced against the toxicity of these agents, and jaw necrosis in particular must be avoided.	A
	Calcium and vitamin D supplementation must be systematically considered when using either denosumab or bisphosphonates.	A
	In patients with neurological symptoms, spinal surgery or decompressive radiotherapy might be indicated as emergency interventions. High-dose corticosteroids must always be initially considered.	A

A* Upgraded following panel consensus.

ADT = androgen deprivation therapy; DRE = digital rectal examination; EBRT = external beam radiation therapy; HIFU = high-intensity focused ultrasound; LHRH = luteinising-hormone-releasing hormone; (e)LND = (extended) lymph node dissection; mCRPC = metastatic castrate-resistant prostate cancer; MRI = magnetic resonance imaging; NHT = neoadjuvant hormonal therapy; NSAA = non-steroidal anti-androgen; PSA-DT = PSA doubling time; RP = radical prostatectomy; TURP = transurethral resection of the prostate.

2. METHODS

2.1 Data identification and evidence sources

For all chapters of this 2015 Guidelines document, the literature has been assessed and updated. In this 2015 EAU Guidelines compilation, all standard information on levels of evidence (LE) and grading of recommendations (GR) has been taken out of the individual guidelines topics for the sake of brevity. This information is included in the introductory section of this print.

2.2 Review

This document was subjected to double-blind peer review prior to publication.

2.3 Future plans

For their 2016 update, the Guidelines Panel aim to present the results of a number of ongoing systematic reviews.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Prostate cancer (PCa) is the most common cancer in elderly males (> 70 years of age) in Europe. It is a major health concern, especially in developed countries with their greater proportion of elderly men in the general population. The incidence is highest in Northern and Western Europe (> 200 per 100,000), while rates in Eastern and Southern Europe have showed a continuous increase [4]. There is still a survival difference between men diagnosed in Eastern Europe and those in the rest of Europe [5]. Overall, during the last decade, the 5-year relative survival percentages for PCa steadily increased from 73.4% in 1999-2001 to 83.4% in 2005-2007 [5].

With the expected increase in the life expectancy of men and in the incidence of prostate cancer, the disease's economic burden in Europe is also expected to increase substantially. It is estimated that the total economic costs of PCa in Europe exceed € 8.43 billion [6], with a high proportion of the costs of PCa care occurring in the first year after diagnosis. In European countries with available data (UK, Germany, France, Italy, Spain, the Netherlands), this amounted to € 106.7-179.0 million for all PCa patients diagnosed in 2006.

3.2 Risk factors and chemoprevention

The factors that determine the risk of developing clinical PCa are not well known, although a few have been identified. There are three well-established risk factors for PCa:

- increasing age;
- ethnic origin;
- heredity.

If one first-line relative has PCa, the risk is at least doubled. If two or more first-line relatives are affected, the risk increases by 5-11-fold [7, 8]. A small subpopulation of men with PCa (about 9%) have true hereditary PCa. This is defined as three or more affected relatives, or at least two relatives who have developed early-onset disease, i.e. before age 55 [8]. Patients with hereditary PCa usually have an onset six to seven years earlier than spontaneous cases, but do not differ in other ways [8].

The frequency of incidentally- and autopsy-detected cancers is roughly the same in different parts of the world [273]. This finding is in sharp contrast to the incidence of clinical PCa, which differs widely between different geographical areas, being high in the USA and northern Europe and low in South-East Asia. However, if Japanese men move from Japan to Hawaii, their risk of PCa increases. If they move to California their risk increases even more, approaching that of American men [9].

These findings indicate that exogenous factors affect the risk of progression from so-called latent PCa to clinical PCa. Factors such as the foods consumed, the pattern of sexual behaviour, alcohol consumption, exposure to ultraviolet radiation, chronic inflammation [10, 11] and occupational exposure have all been discussed as being aetiologically important [11]. PCa may be an ideal candidate for exogenous preventive measures, such as dietary and pharmacological prevention, due to the following specific features:

- high prevalence
- long latency
- endocrine dependency
- availability of serum markers (PSA)
- the histological precursor lesion prostatic intraepithelial neoplasia [10].

Nevertheless, there is currently no evidence to suggest that dietary interventions would reduce the risk of PCa. The outcome of the Selenium and Vitamin E Cancer Prevention Trial (SELECT) was negative, and therefore vitamin E and selenium are not recommended for the prevention of PCa [12]. Similarly, a meta-analysis of eight randomised controlled trials comparing lycopene with placebo did not identify a significant decrease in the incidence of PCa [13].

Metabolic syndrome is weakly and non-significantly associated with the risk of PCa, but associations vary with geography. Among single components of the syndrome (body mass index, dysglycaemia or dyslipidaemia, high triglycerides, low HDL cholesterol) only hypertension and waist circumference >102 cm were associated with a significantly greater risk of PCa, increasing it by 15% ($p = 0.035$) and 56% ($p = 0.007$), respectively [14]. Currently, there are no data to suggest that medical intervention would effectively reduce progression of PCa. Several 5-alpha-reductase inhibitors (5-ARIs) have been studied to assess their effect on reducing the risk of developing PCa. Although it seems that 5-ARIs have a potential benefit in preventing or delaying the development of PCa (~25%, only of Gleason 6 cancer), this must be weighed against treatment-related side-effects as well as the potential increased risk of high-grade PCa [15-17]. None of the available 5-ARIs have been approved for this indication.

In summary, hereditary factors are important in determining the risk of developing clinical PCa, while exogenous factors may have an important impact on the risk of progression. There is, as yet, insufficient evidence to recommend lifestyle changes (such as a reduced intake of animal fat and an increased intake of fruit, cereals and vegetables) in order to decrease the risk [18].

3.2.1 **Guideline for preventative measures**

At this moment in time no definitive recommendation can be provided for preventive measures due to the lack of conclusive data.

4. CLASSIFICATION AND STAGING SYSTEMS

4.1 **Classification**

The objective of a tumour classification system is to combine patients with a similar clinical outcome. This allows for the design of clinical trials on relatively homogeneous patient populations, the comparison of clinical and pathological data obtained from different hospitals across the world and to make recommendations on their treatment. Throughout this guideline we made use of the 2009 TNM classification for staging of PCa (Table 4.1.1) [19] and the EAU risk group classification essentially based on D'Amico's classification system for PCa (Table 4.1.2) [20]. The latter classification is based on the grouping of patients with a similar risk of biochemical recurrence (BCR) after surgery or external beam radiotherapy.

Table 4.1.1: Tumour Node Metastasis (TNM) classification of PCa [19]

T - Primary tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
T1	Clinically inapparent tumour not palpable or visible by imaging
T1a	Tumour incidental histological finding in 5% or less of tissue resected
T1b	Tumour incidental histological finding in more than 5% of tissue resected
T1c	Tumour identified by needle biopsy (e.g. because of elevated prostate-specific antigen (PSA) level)
T2	Tumour confined within the prostate ¹
T2a	Tumour involves one half of one lobe or less
T2b	Tumour involves more than half of one lobe, but not both lobes
T2c	Tumour involves both lobes
T3	Tumour extends through the prostatic capsule ²
T3a	Extracapsular extension (unilateral or bilateral) including microscopic bladder neck involvement
T3b	Tumour invades seminal vesicle(s)
T4	Tumour is fixed or invades adjacent structures other than seminal vesicles: external sphincter, rectum, levator muscles, and/or pelvic wall
N - Regional lymph nodes³	
NX	Regional lymph nodes cannot be assessed
N0	No regional lymph node metastasis
N1	Regional lymph node metastasis ⁴
M - Distant metastasis⁵	
MX	Distant metastasis cannot be assessed
M0	No distant metastasis
M1	Distant metastasis
M1a	Non-regional lymph node(s)
M1b	Bone(s)
M1c	Other site(s)

¹ Tumour found in one or both lobes by needle biopsy, but not palpable or visible by imaging, is classified as T1c.

² Invasion into the prostatic apex, or into (but not beyond) the prostate capsule, is not classified as pT3, but as pT2.

³ The regional lymph nodes are the nodes of the true pelvis, which essentially are the pelvic nodes below the bifurcation of the common iliac arteries.

⁴ Laterality does not affect the N-classification

⁵ When more than one site of metastasis is present, the most advanced category should be used.

Table 4.1.2: EAU risk groups for biochemical recurrence of localised and locally advanced prostate cancer

	Low-risk	Intermediate-risk	High-risk	
Definition	PSA < 10 ng / mL and GS < 7 and cT1-2a	PSA 10-20 ng /mL or GS 7 or cT2b	PSA > 20 ng / mL or GS > 7 or cT2c	any PSA any GS cT3-4 or cN+
	Localised			Locally advanced

5. DIAGNOSTIC EVALUATION

5.1 Screening and early detection

Population or mass screening is defined as the systematic examination of asymptomatic men (at risk) and is usually initiated by health authorities. In contrast, early detection or opportunistic screening consists of individual case findings, which are initiated by the person being screened (patient) and/or his physician. The co-primary endpoints of both types of screening are:

- reduction in mortality due to PCa;
- at least, a maintained QoL as expressed by quality-of-life-adjusted gain in life years (QUALYs).

Prostate cancer mortality trends range widely from country to country in the industrialised world [21]. Mortality due to PCa has decreased in most Western countries but the magnitude of the reduction varies between countries. The reduced mortality seen recently in the USA is considered to be partly due to a widely adopted aggressive PCa screening policy [22]. However, there is still no level 1 evidence that prostate-specific antigen (PSA) screening reduces mortality due to PCa [23].

Currently, screening for PCa is one of the most controversial topics in the urological literature [24]. Three large prospective RCTs published data on screening in 2009 [25-27]. Heated discussions and debates resulted in many conflicting positions and policy papers. Some authors argue that the use of current AUA guidelines recommendations for screening may lead to missing a substantial number of men with aggressive disease [28, 29]. The potential impact of this topic would necessitate the highest level of evidence produced through a systematic literature search of all published trials or cohorts summarised in a structured meta-analysis. Subgroup analyses of cohorts that are part of large trials, or mathematical projections, cannot provide the quality of evidence needed to appropriately address this clinical question.

The main summary of findings from literature published on PCa screening is the Cochrane review published in 2013 [23]. This review was based on an up-to-date systematic literature search until November 2012 and is an update of a 2010 paper with the same methodology. Its findings are as follows:

- Screening was associated with an increased diagnosis of PCa (RR: 1.3; 95% CI: 1.02-1.65).
- Screening was associated with more localised disease (RR: 1.79; 95% CI: 1.19-2.70) and less advanced PCa (T3-4, N1, M1) (RR: 0.80; 95% CI: 0.73-0.87).
- From the results of five RCTs, representing more than 341,000 randomised men, no PCa-specific survival benefit was observed (RR: 1.00; 95% CI: 0.86-1.17). This was the main objective of all the large trials.
- From the results of four available RCTs, no overall survival followed by (OS) benefit was observed (RR: 1.00; 95% CI: 0.96-1.03).

Moreover, screening was associated with minor and major harms such as overdiagnosis and overtreatment. Surprisingly, the diagnostic tool (i.e. the biopsy) was not associated with any mortality in the selected papers, which is in contrast with other known data [16, 17].

The impact on the patient's overall QoL is still unclear. It appears to be minimal in some subgroup analyses [30], but significant in others [31]. This has led to strong advice against population-based systematic screening in all countries, including Europe.

Since 2013, the ERSPC data have been updated with a 13 years of follow up (see Table 5.1.1) [32]. The key message is that with extended follow up, the mortality reduction remains unchanged (21%, and 29% after non-compliance adjustment). However the number needed to screen and to treat is decreasing, and is now below the number needed to screen observed in breast cancer trials [33].

Table 5.1.1 Follow-up data from the ERSPC study [32]

	Number needed to screen	Number needed to treat
9 years of follow-up	1410	48
11 years of follow-up	979	35
13 years of follow-up	781	27

Thus, an individualised risk-adapted strategy for early detection might be offered to a well-informed man with a least 10-15 years of individual life expectancy. However, this approach may still be associated with a substantial risk of overdiagnosis. It is therefore important to carefully identify those patient cohorts likely to benefit most from individual early diagnosis, taking into account the potential balances and harms involved.

Men at elevated risk of having PCa are those > 50 years, or with a family history of PCa and age > 45 years, or African-Americans [34]. In addition, men with PSA > 1 ng/mL at 40 years and > 2 ng/mL at 60 years [35, 36] are also at increased risk of PCa metastasis or death several decades later. Recently, as for breast cancer, a genetic abnormality likely to be associated with an increased risk has been shown prospectively [37]. Its everyday use requires further studies and cannot yet be recommended.

Risk calculators may be useful in helping to decide (on an individual basis) the potential risk of cancer whilst reducing the number of unnecessary biopsies. Several tools exist developed from several cohorts (from the PCPT cohort: PCPTRC 2.0: <http://deb.uthscsa.edu/URORiskCalc/Pages/calcs.jsp>; from the ERSPC cohort: <http://www.prostatecancer-riskcalculator.com/seven-prostate-cancer-risk-calculators>, from a local Canadian cohort: <http://sunnybrook.ca/content/?page=occ-prostatecalc>, among others). Since none has clearly shown superiority it is impossible to provide a recommendation and it remains a personal decision which one to use [38].

Early baseline testing could be used to detect men at risk and in need of further follow-up. However, the long-term benefit for survival and QoL of such an approach remains to be proven at a population level.

Informed men requesting an early diagnosis should be given a PSA test and undergo a DRE [39]. The optimal intervals for PSA testing and DRE follow-up are unknown, and it has varied between several prospective trials. A risk-adapted strategy might be considered based on the initial PSA level. This could be every 2 years for those initially at risk, or postponed up to 8 years in those not at risk.

The age at which attempts to make an early diagnosis of PCa should be stopped remains controversial, but is influenced by an individual's life expectancy. Men who have less than a 15-year life expectancy are unlikely to benefit based on the PIVOT and the ERSPC trials. Furthermore, although there is no simple tool to evaluate individual life expectancy, co-morbidity is at least as important as age. A detailed review can be found in the section on senior adults and in the recently updated SIOG guidelines [40].

Based on the tools currently available, an individualised strategy will diagnose many insignificant lesions (above 50% in some trials), most of which will not require any form of active treatment (Section 7.1, Deferred treatment). It is important to realise that breaking the link between diagnosis and active treatment is the only way to decrease overtreatment, while still maintaining the potential benefit of individual early diagnosis for men requesting it.

From a public health point of view, mass screening of PCa is not indicated. However, early diagnosis on an individual basis is possible based on DRE and PSA testing. Individual patient screening requires informed consent from the patient following a full discussion with their physician on the pros and cons of the complete procedure, taking into account the patient's risk factors, age and life expectancy. The interval for follow-up screening depends on age and baseline PSA level.

5.1.1 Guidelines for screening and early detection

	LE	GR
An individualised risk-adapted strategy for early detection might be offered to a well-informed man with a good performance status and at least 10-15 years of life expectancy.	3	B
Early PSA testing should be offered to men at elevated risk for PCa. Risk groups are: <ul style="list-style-type: none"> men over 50 years of age men over 45 years of age and a family history of PCa African-Americans men with a PSA level of > 1 ng/mL at 40 years of age men with a PSA level of > 2 ng/mL at 60 years of age 	2b	A
A risk-adapted strategy might be considered (based on initial PSA level), which may be every 2 years for those initially at risk, or postponed up to 8 years in those not at risk.	3	C
The age at which early diagnosis of PCa should be stopped is influenced by life expectancy and performance status; men who have < 15-year life expectancy are unlikely to benefit based on the PIVOT and the ERSPC trials.	3	A

5.2 Clinical diagnosis

Prostate cancer is usually suspected on the basis of digital rectal examination (DRE) and/or prostate-specific antigen (PSA) levels. Definitive diagnosis depends on histopathological verification of adenocarcinoma in prostate biopsy cores or specimens from TURP or prostatectomy for benign prostatic enlargement (BPE).

5.2.1 Digital rectal examination

Most prostate cancers are located in the peripheral zone and may be detected by DRE when the volume is ≥ 0.2 mL. In ~18% of cases, PCa is detected by suspect DRE alone, irrespective of PSA level [41]. Suspect DRE in patients with PSA level ≤ 2 ng/mL has a positive predictive value of 5-30% [42]. Abnormal DRE is associated with an increased risk of higher Gleason score and is an indication for biopsy [43, 44].

5.2.2 Prostate-specific antigen

The use of PSA as a serum marker has revolutionised PCa diagnosis [45]. PSA is organ- but not cancer-specific, therefore, it may be elevated in benign prostatic hypertrophy (BPH), prostatitis and other non-malignant conditions. As an independent variable, PSA is a better predictor of cancer than DRE or transrectal ultrasound (TRUS) [46].

There are no agreed standards defined for measuring PSA [47]. PSA is a continuous parameter, with higher levels indicating greater likelihood of PCa. Many men may harbour PCa despite having low serum PSA [48]. Table 5.2.1 demonstrates the occurrence of Gleason ≥ 7 PCa at low PSA levels, precluding an optimal PSA threshold for detecting non-palpable but clinically significant PCa. The use of nomograms may help in predicting indolent PCa [49].

Table 5.2.1: Risk of PCa in relation to low PSA values

PSA level (ng/mL)	Risk of PCa (%)	Risk of Gleason ≥ 7 PCa (%)
0.0-0.5	6.6	0.8
0.6-1.0	10.1	1.0
1.1-2.0	17.0	2.0
2.1-3.0	23.9	4.6
3.1-4.0	26.9	6.7

5.2.2.1 PSA density

PSA density is the level of serum PSA divided by the TRUS-determined prostate volume. The higher the PSA density, the more likely that PCa is clinically significant (see Section 6.1.3).

5.2.2.2 PSA velocity and doubling time

There are two methods of measuring PSA kinetics:

- PSA velocity (PSAV): absolute annual increase in serum PSA (ng/mL/year) [50];
- PSA doubling time (PSA-DT): which measures the exponential increase in serum PSA over time [51].

PSAV and PSA-DT may have a prognostic role in treated PCa [52], but limited diagnostic use because of background noise (total prostate volume, and BPH), different intervals between PSA determinations, and acceleration/deceleration of PSAV and PSA-DT over time. These measurements do not provide additional information compared with PSA alone [53-56].

5.2.2.3 Free/total PSA ratio

Free/total (f/t) PSA ratio is widely used to differentiate BPH from PCa. It stratifies the risk of PCa in men with 4-10 ng/mL total PSA and negative DRE. PCa was detected by biopsy in 56% of men with f/t PSA < 0.10 , but in only 8% with f/t PSA > 0.25 [57]. f/t PSA is of no clinical use if total serum PSA is > 10 ng/mL or during follow-up of known PCa.

f/t PSA must be used cautiously because it may be adversely affected by several preanalytical and clinical factors (e.g., instability of free PSA at 4°C and room temperature, variable assay characteristics, and concomitant BPH in large prostates) [58].

5.2.2.4 Prostate Health Index (PHI) test

The Prostate Health Index (PHI) test is a recently approved diagnostic blood test, combining free and total PSA and the (-2) pro PSA isoform (p2PSA), intended to reduce the number of unnecessary prostate biopsies in PSA tested men. A few prospective multicentre studies demonstrated that the PHI test not only outperforms free and total PSA PCa detection, but has an improved prediction of clinically significant PCa, both in men with a PSA between 4-10 ng/mL and between 2-10 ng/mL. The PHI test may therefore also have a role in monitoring men under active surveillance [59]. Its clinical impact is, as yet undetermined, given the slight net benefit for clinical decision-making [60].

5.2.2.5 *PCA3 marker*

PCA3 is a prostate-specific, non-coding mRNA biomarker that is detectable in urine sediments obtained after three strokes of prostatic massage during DRE. The ProgenSA urine test for PCA3 is now commercially available. PCA3 is superior to total and percent-free PSA for detection of PCa in men with elevated PSA as it shows significant increases in the area under the receiver-operator characteristic curve for positive biopsies [61-64].

PCA3 score increases with PCa volume, but there are conflicting data about whether it independently predicts Gleason score, and its use for monitoring in active surveillance is unconfirmed [65]. Currently, the main indication for the ProgenSA test is to determine whether repeat biopsy is needed after an initially negative biopsy.

5.2.3 **Prostate biopsy**

5.2.3.1 *Baseline biopsy*

The need for prostate biopsy is based on PSA level and/or suspicious DRE. Age, potential comorbidity, and therapeutic consequences should also be considered and discussed beforehand [66]. Risk stratification is a potential tool for reducing unnecessary biopsies [66].

Limited PSA elevation alone, should not prompt immediate biopsy. PSA level should be verified after a few weeks using the same assay under standardised conditions (i.e., no ejaculation, manipulations, and urinary tract infections) in the same laboratory [67, 68]. Empiric use of antibiotics in an asymptomatic patient in order to lower the PSA should not be undertaken [69].

Ultrasound-guided biopsy is now the standard of care. A transrectal approach is used for most prostate biopsies, although some urologists prefer a perineal approach. Cancer detection rates are comparable with both approaches [70, 71].

5.2.3.2 *Repeat biopsy after previously negative biopsy*

The indications for repeat biopsy are:

- rising and/or persistently elevated PSA (see Table 5.2 for risk estimates);
- suspicious DRE, 5-30% cancer risk [41, 42];
- atypical small acinar proliferation (i.e., atypical glands suspicious for cancer), 40% risk [72];
- extensive (multiple biopsy sites, i.e., ≥ 3) high grade prostatic intraepithelial neoplasia (HGPIN), ~30% risk [72, 73];
- A few atypical glands immediately adjacent to high grade prostatic intraepithelial neoplasia (i.e., PINATYP), ~50% risk [74].

Isolated high-grade PIN in one or two biopsy sites is no longer an indication for repeat biopsy [75].

5.2.3.3 *Saturation biopsy*

The incidence of PCa detected by saturation repeat biopsy (> 20 cores) is 30-43% and depends on the number of cores sampled during earlier biopsies [76]. Saturation biopsy may be performed with the transperineal technique, which detects an additional 38% of PCa. The high rate of urinary retention (10%) is a drawback [77].

5.2.3.4 *Sampling sites and number of cores*

On baseline biopsies, the sample sites should be bilateral from apex to base as far posterior and lateral as possible in the peripheral gland. Additional cores should be obtained from suspect areas by DRE/TRUS.

Sextant biopsy is no longer considered adequate. For prostate volume 30-40 mL, ≥ 8 cores should be sampled. Ten to 12 core biopsies are recommended [78], with > 12 cores not being significantly more conclusive [79, 80].

5.2.3.5 *Diagnostic transurethral resection of the prostate*

Transurethral resection of the prostate (TURP) should not be used as a tool for cancer detection [81].

5.2.3.6 *Seminal vesicle biopsy*

Indications for seminal vesicle (staging) biopsies are poorly defined. At PSA > 15 ng/mL, the odds of tumour involvement are 20-25% [82]. Seminal vesicle staging biopsy is only useful if it has a decisive impact on treatment, such as ruling out radical tumour resection or radiotherapy. Its added value compared with multiparametric MRI (mpMRI) is questionable.

5.2.3.7 Transition zone biopsy

Transition zone sampling during baseline biopsies has a low detection rate and should be confined to repeat biopsies [83].

5.2.3.8 Antibiotics prior to biopsy

Oral or intravenous antibiotics are state-of-the-art. Quinolones are the drugs of choice, with ciprofloxacin being superior to ofloxacin [84]. Increased quinolone resistance [85] is associated with a rise in severe post-biopsy infection [86].

5.2.3.9 Local anaesthesia prior to biopsy

Ultrasound-guided periprostatic block is state-of-the-art [87]. It is not important whether the depot is apical or basal. Intrarectal instillation of local anaesthesia is inferior to periprostatic infiltration [88].

5.2.3.10 Fine-needle aspiration biopsy

Fine-needle aspiration biopsy is no longer state-of-the-art.

5.2.3.11 Complications

Biopsy complications are listed in Table 5.2.2 [89]. Severe postprocedural infections were initially reported in < 1% of cases, but have increased as a consequence of antibiotic resistance [90].

Low-dose aspirin is no longer an absolute contraindication [91].

Table 5.2.2: Percentage of complications per biopsy session, irrespective of the number of cores

Complications	Percentage of patients affected
Haemospermia	37.4
Haematuria > 1 day	14.5
Rectal bleeding < 2 days	2.2
Prostatitis	1.0
Fever > 38.5°C	0.8
Epididymitis	0.7
Rectal bleeding > 2 days +/- surgical intervention	0.7
Urinary retention	0.2
Other complications requiring hospitalisation	0.3

5.2.4 Role of imaging

5.2.4.1 TRUS

Classic hypoechogenicity in the peripheral prostate is not always seen. Grey-scale TRUS is not reliable at detecting PCa [92]. Thus, there is no evidence that targeted biopsies can replace systematic biopsies. New sonographic modalities such as sonoelastography, contrast-enhanced ultrasound or computerised ultrasound (Histoscanning™) are being investigated. There is not currently enough evidence for their routine use.

5.2.4.2 Multiparametric MRI (mpMRI)

Correlation with radical prostatectomy (RP) shows that mpMRI, associating T2-weighted imaging with diffusion-weighted imaging, dynamic contrast-enhanced imaging, or H1-spectroscopy, has excellent sensitivity for Gleason score ≥ 7 cancers (Table 5.2.3) [93-96].

Table 5.2.3: PCa detection rates (%) by mpMRI by tumour volume and Gleason score [96]

Gleason score	Tumour volume (mL)		
	< 0.5	0.5-2	> 2
GS6	21-29%	43-54%	67-75%
GS7	63%	82-88%	97%
GS > 7	80%	93%	100%

mpMRI may detect anterior tumours missed by systematic biopsy [97, 98]. In 265 patients undergoing repeat biopsy, mpMR-guided samples were positive in 41%, and 87% of the cancers were clinically significant [99].

Biopsies targeted on MR abnormalities also seem to evaluate PCa aggressiveness better than systematic biopsy [100]. Although some authors proposed mpMRI as a triage test for biopsy candidates, to increase

detection of aggressive cancers and reduce over-detection of non-significant foci [101-103], only a few controlled trials have currently been published [104-106]. A recent systematic review concluded that, whereas there was currently not enough evidence to recommend mpMRI before a first set of prostate biopsies, the use of targeted biopsy often achieved significantly higher cancer detection rate in the repeat biopsy setting [107].

Inter-reader variability remains a concern with mpMRI. The Prostate Imaging Reporting and Data System (PIRADS) scoring system has been recently proposed to standardise mpMRI interpretation [108], but two independent evaluations suggested that it did not improve inter-reader variability as compared to subjective scoring [109, 110].

5.2.4.3 Guidelines for imaging

	LE	GR
When clinical suspicion of PCa persists in spite of negative biopsies, MRI-targeted biopsies are recommended.	2b	B

GR = grade of recommendation; LE = level of evidence; MRI = magnetic resonance imaging.

5.2.5 Pathology of prostate needle biopsies

5.2.5.1 Processing

Prostate core biopsies from different sites are processed separately. Before processing, the number and length of the cores are recorded. The length of biopsy tissue significantly correlates with PCa detection rate [111]. To achieve optimal flattening and alignment, a maximum of three cores should be embedded per tissue cassette, and sponges or paper used to keep the cores stretched and flat [3, 112]. To optimise detection of small lesions, paraffin blocks should be cut at three levels [83] and intervening unstained sections are kept for immunohistochemistry.

5.2.5.2 Microscopy and reporting

Diagnosis of PCa is based on histology. The diagnostic criteria include features pathognomonic of cancer, major and minor features favouring cancer and features against cancer. Ancillary staining and additional (deeper) sections should be considered if a suspect lesion is identified [113-115]. Diagnostic uncertainty is resolved by intradepartmental or external consultation [113]. Table 5.2.4 lists the recommended terminology for reporting prostate biopsies [3].

Table 5.2.4: Recommended terminology for reporting prostate biopsies [3]

•	Benign/negative for malignancy. If appropriate, include a description
•	Active inflammation
•	Granulomatous inflammation
•	High-grade PIN
•	High-grade PIN with atypical glands, suspicious for adenocarcinoma (PINATYP)
•	Focus of atypical glands/lesion suspicious for adenocarcinoma/atypical small acinar proliferation, suspicious for cancer
•	Adenocarcinoma

Each biopsy site should be reported individually, including its location (in accordance with site of sampling) and histopathologic findings, which include the histological type and the International Society of Urological Pathology (ISUP) 2005 Gleason score (i.e., 2005 ISUP Modified Gleason System) [116]. As compared to the traditional Gleason grading, the ISUP 2005 Gleason score improved the concordance of the grading of the corresponding prostatectomy specimens [117].

The (2005 ISUP modified) Gleason score of biopsy-detected PCa comprises the Gleason grade or pattern of the most extensive (primary pattern) pattern, plus the second most common pattern (secondary pattern), if two are present. If one pattern is present, double it to yield the Gleason score. For three grades, the Gleason score comprises the most common grade plus the highest grade, irrespective of its extent. When the carcinoma is largely grade 4/5, identification of < 5% of Gleason grade 2 or 3 glands should not be incorporated in the Gleason score. A Gleason score ≤ 4 should not be given on prostate biopsies [116]. Intraductal carcinoma, lymphovascular invasion and extraprostatic extension must be reported. In addition to reporting the carcinoma features for each biopsy, an overall Gleason score based on the carcinoma-positive biopsies can be provided.

The proportion of carcinoma-positive cores as well as the extent of tumour involvement per biopsy core

correlates with the Gleason score, tumour volume, surgical margins and pathologic stage in radical prostatectomy (RP) specimens and predicts BCR, post-prostatectomy progression and radiation therapy failure. These parameters are included in nomograms created to predict pathologic stage and seminal vesicle invasion after RP and RT failure [118-120]. A pathology report should therefore provide both the proportion of carcinoma-positive cores and the extent of cancer involvement for each core. The length in mm and percentage of carcinoma in the biopsy have equal prognostic impact [121]. An extent of > 50% of adenocarcinoma in a single core is used in some active surveillance protocols as a cut off [122] triggering immediate treatment vs. active surveillance in patients with Gleason score 6.

A prostate biopsy that does not contain glandular tissue should be reported as diagnostically inadequate.

5.2.6 **Histopathology of radical prostatectomy specimens**

5.2.6.1 *Processing of radical prostatectomy specimens*

Histopathological examination of RP specimens describes the pathological stage, histopathological type, grade and surgical margins of PCa. It is recommended that RP specimens are totally embedded, to enable assessment of cancer location, multifocality and heterogeneity. For cost-effectiveness, partial embedding may also be considered, particularly for prostates > 60 g. The most accepted method includes complete embedding of the posterior prostate, and a single mid-anterior left and right section. Compared with total embedding, partial embedding detected 98% of PCa with a Gleason score ≥ 7 and accurate staging in 96% of cases [123].

Entire RP specimens are inked upon receipt in the laboratory, to demonstrate the surgical margins. Specimens are fixed by immersion in buffered formalin for at least 24 hours, preferably before slicing. Fixation can be enhanced by injecting formalin, which provides more homogeneous fixation and sectioning after 24 h [124]. After fixation, the apex and the base (bladder neck) are removed and cut into (para)sagittal or radial sections; the shave method is not recommended [116]. The remainder of the specimen is cut in transverse, 3-4-mm sections, perpendicular to the long axis of the urethra. The resultant tissue slices can be embedded and processed as whole-mounts or after quadrant sectioning. Whole-mounts provide better topographic visualisation, faster histopathological examination and better correlation with preoperative imaging, although they are more time-consuming and require specialist handling. For routine sectioning, the advantages of whole mounts do not outweigh their disadvantages.

5.2.6.1.1 Guidelines for processing prostatectomy specimens

	LE	GR
Total embedding is preferred, by conventional (quadrant) or whole-mount sectioning.	3	C
The entire surface should be inked before cutting, to evaluate the surgical margin.	3	A
The apex and base should be examined separately using the cone method with sagittal or radial sectioning.	3	A

GR = grade of recommendation; LE = level of evidence.

5.2.6.2 *RP specimen report*

The pathology report provides essential information on the prognostic characteristics relevant for clinical decision-making (Table 5.2.5). As a result of the complex information provided on each RP specimen, the use of synoptic(-like) or checklist reporting is recommended (Table 5.2.6). Synoptic reporting results in more transparent and complete pathology reporting [125].

Table 5.2.5: Information provided by the pathology report

Histopathological type: > 95% of PCa represents conventional (acinar) adenocarcinoma.
Grading according to Gleason score (or therapy-related changes).
Tumour (sub)staging and surgical margin status: location and extent of extraprostatic extension, presence of bladder neck invasion, laterality of extraprostatic extension or seminal vesicle invasion, location and extent of positive surgical margins.
Additional information may be provided on multifocality, and diameter/volume and zonal location of the dominant tumour.

Table 5.2.6: Example checklist: reporting of prostatectomy specimens

5.2.6.2.1 Gleason score

Grading of conventional prostatic adenocarcinoma using the (modified) Gleason system [116] is the strongest prognostic factor for clinical behaviour and treatment response. The Gleason score is incorporated in nomograms that predict disease-specific survival after prostatectomy [126].

5.2.6.2.2 Interpreting Gleason score

The Gleason score is the sum of the most and second-most dominant (in terms of volume) Gleason grade. If only one grade is present, the primary grade is doubled. If a grade comprises $\leq 5\%$ of the cancer volume it is not incorporated in the Gleason score (5% rule). The primary and secondary grades are reported in addition to the Gleason score. A global Gleason score is given for multiple tumours, but a separate tumour focus with a higher Gleason score should also be mentioned. Tertiary Gleason grade 4 or 5, particularly if $> 5\%$ of the PCa volume, is an unfavourable prognostic indicator for BCR. The tertiary grade and its approximate proportion of the cancer volume should also be reported [127] in addition to the Gleason score.

5.2.6.2.3 Definition of extraprostatic extension

Extraprostatic extension is defined as carcinoma mixed with periprostatic adipose tissue, or tissue that extends beyond the prostate gland boundaries (e.g., neurovascular bundle, anterior prostate). Microscopic bladder neck invasion is considered extraprostatic extension. It is useful to report the location and extent of extraprostatic extension because the latter is related to recurrence risk [128].

There are no internationally accepted definitions of focal or microscopic, vs. non-focal or extensive extraprostatic extension. Some describe focal as a few glands [129] or extension as < 1 high-power field (HPF) [130], whereas others measure the depth of extent in millimetres [131].

At the apex of the prostate, tumour mixed with skeletal muscle does not constitute extraprostatic extension. In the bladder neck, microscopic invasion of smooth muscle fibres is not equated to bladder wall invasion, i.e., not as pT4, because it does not carry independent prognostic significance for PSA recurrence [132, 133] and should be recorded as extraprostatic extension (pT3a). A positive margin at the bladder neck should be reported as extraprostatic extension (pT3a) with positive margin, and not as pT4.

Stage pT4 is only assigned when the tumour invades the bladder muscle wall as determined macroscopically [134].

5.2.6.3 Prostate cancer volume

The independent prognostic value of PCa volume in RP specimens has not been established [130, 135-138]. Nevertheless, a cut-off of 0.5 mL is commonly used to distinguish insignificant from clinically relevant cancer [135]. Improvement in prostatic radioimaging allows more accurate preoperative measurement of cancer volume. It is recommended that at least the diameter/volume of the dominant tumour nodule should be assessed, or a rough estimate of the percentage of cancer tissue provided [139].

5.2.6.4 Surgical margin status

Surgical margin is an independent risk factor for BCR. Margin status is positive if tumour cells are in contact with the ink on the specimen surface. Margin status is negative if tumour cells are close to the inked surface [136] or at the surface of the tissue lacking ink.

In tissues that have severe crush artefacts, it may not be possible to determine margin status [140]. Surgical margin is separate from pathological stage, and a positive margin is not evidence of extraprostatic extension [141]. There is insufficient evidence to prove a relationship between margin extent and recurrence risk [130]. However, some indication must be given of the multifocality extent of margin positivity, such as the linear extent in mm of involvement: focal, ≤ 1 mm vs. extensive, > 1 mm [142], or number of blocks with positive margin involvement.

5.2.6.5 Other factors

According to the College of American Pathologists' consensus statement [143], additional potential biomarkers have not been sufficiently studied to demonstrate their additional prognostic value and clinical usefulness outside the standard patient care setting, including perineural invasion, neuroendocrine differentiation, microvessel density, nuclear roundness, chromatin texture, other karyometric factors, proliferation markers, and PSA derivatives.

5.2.7 Guidelines for the clinical diagnosis of prostate cancer

	LE	GR
Transurethral resection of the prostate should not be used as a tool for cancer detection.	2a	A
PCa should be graded according to the ISUP 2005 modified Gleason grading system.	2a	A
Biopsy decision should be based on PSA testing and DRE.	2b	A
Transition zone biopsies are not recommended initially due to low detection rates.	2b	B
For initial diagnosis, a core biopsy of 10-12 systematic transrectal or transperineal peripheral zone biopsies should be performed under ultrasound guidance.	2a	B
Transrectal prostate needle biopsies should be taken under antibiotic protection.	1b	A
Local anaesthetic by periprostatic infiltration is recommended for prostate needle biopsies.	1a	A
Prostate core biopsies from different sites should be submitted separately for processing and pathology reporting.	3	A
Processing and reporting of prostatectomy specimens should follow the guidelines of the 2010 ISUP consensus meeting.	3	A
One set of repeat biopsies is warranted for persistent indications for PCa (abnormal DRE, elevated PSA or histopathological findings suggestive of malignancy at initial biopsy).	2a	B

DRE = digital rectal examination; GR = grade of recommendation; ISUP = International Society of Urological Pathology; LE = level of evidence; PSA = prostate-specific antigen.

5.3 Diagnosis: Clinical staging

The extent of PCa is evaluated by DRE and PSA, and may be supplemented with bone scanning and computed tomography (CT) or mpMRI.

5.3.1 T-staging

5.3.1.1 Definitions

Extraprostatic extension is defined as carcinoma mixed with periprostatic adipose tissue, or tissue that extends beyond the prostate gland (e.g., neurovascular bundle, anterior prostate, or bladder neck) and corresponds to stage T3a. It is to be distinguished from seminal vesicles (SVI) invasion that corresponds to stage T3b (see Section 5.2 for details).

5.3.1.2 DRE, PSA level and biopsy findings

The first level of assessment is local tumour stage because the distinction between organ-confined (T1/T2) and extraprostatic (T3/T4) disease affects treatment decisions. DRE is positively correlated with tumour stage

in < 50% of cases [144], although it often underestimates tumour extension. More extensive T-staging is only recommended if it directly affects treatment decisions

Serum PSA levels increase with tumour stage, although they are limited for accurate prediction of final pathological stage. PSA is produced by benign and malignant tissue, thus, there is no direct relationship between serum PSA and clinicopathological tumour stage [145]. In prostate needle biopsy, the percentage of cancerous tissue is a strong predictor of positive surgical margins, SVI, and non-organ-confined disease [146]. An increase in tumour-positive biopsies is an independent predictor of extraprostatic extension, margin involvement, and lymph node invasion [147]. Serum PSA, Gleason score, and T stage are more useful together than alone in predicting final pathological stage [126, 148]. These models may help to select candidates for nerve-sparing surgery and lymphadenectomy (Section 7.2).

SVI is predictive of local relapse and distant metastatic failure. SV biopsies can improve preoperative staging accuracy [149]. This is not recommended for first-line examination, but is reserved for patients with high risk of SVI, in whom a positive biopsy would modify treatment. Patients with T stage > 2a and serum PSA > 10 ng/mL are candidates for SV biopsy [150, 151]. Patients with positive biopsies from the base of the prostate are more likely to have positive SV biopsies [152].

Transperineal 3D prostate mapping biopsy (PMB) is an alternative to transrectal biopsies because it provides more accurate tumour localization, extent and Gleason grading [153], and has acceptable morbidity.

5.3.1.3 *Transrectal ultrasound (TRUS)*

Only 60% of tumours are visible with TRUS, and 40% are undetectable due to isoechogenicity. TRUS is no more accurate at predicting organ-confined disease than DRE [154, 155]. Combined DRE and TRUS can detect T3a PCa more accurately than either method alone [156].

3D-TRUS is claimed to have better staging accuracy than 2D techniques [157]. Greater sensitivity for cancer detection is achieved by the addition of power colour Doppler and contrast agents [158-160]. All TRUS techniques are largely operator-dependent and cannot differentiate between T2 and T3 tumours with sufficient accuracy to be recommended for routine staging.

5.3.1.4 *Multiparametric magnetic resonance imaging (MRI)*

T2-weighted imaging (WI) remains the most useful method for local staging on MRI. At 1.5T (Tesla), MRI has low sensitivity for detecting extraprostatic extension of carcinoma (22-82%) or SVI (0-71%), but higher specificity (61-100% and 62-100%, respectively) [161-176]. Global MRI accuracy for distinguishing T1/T2 stages from T3 stage is 50-85% [163-165, 171, 172, 177-180]. These disappointing results are because MRI cannot detect microscopic extra-prostatic extension. Its sensitivity increases with the radius of extension within periprostatic fat. In one study, the EEC detection rate increased from 14 to 100% when the radius of extension increased from < 1 mm to > 3 mm [163]. In another study, MRI sensitivity, specificity and accuracy for detecting pT3 stage were, 40, 95 and 76%, respectively, for focal (i.e. microscopic) extra-prostatic extension, and 62, 95 and 88% for extensive extra-prostatic extension [171].

An endorectal coil improves staging accuracy at 1.5T, and accuracy of 77-83% has been shown for combined endorectal and external coils vs. 59-68% for external coil alone [174, 181]. Dynamic contrast-enhanced imaging combined with T2-WI may also improve local staging [172, 175]. The high field strength allows high-resolution T2-WI [182] and results at 3T seem better than at 1.5T [173, 183], even if the experience of the reader remains of paramount importance, MRI accuracy at 3T varies between 67% and 93% depending on the experience of the reader [173]. Even if MRI is not perfect for local staging, it may improve prediction of the pathological stage when combined with clinical data [184, 185].

Given its low sensitivity for focal (microscopic) extra-prostatic extension, mpMRI is not recommended for local staging in low-risk patients [184, 186, 187]. However, mpMRI can still be useful for treatment planning in selected low-risk patients (e.g. candidates for brachytherapy) [188].

5.3.2 *N-staging*

5.3.2.1 *PSA level and biopsy findings*

N-staging should be performed only when it might directly influence treatment decisions. High PSA values, T2b-T3 stage, poor tumour differentiation and perineural invasion are associated with high risk of nodal metastases [126, 189, 190]. Measurement of PSA alone is unhelpful in predicting lymph node metastases.

Nomograms or Partin tables can define patients at low risk (< 10%) of nodal metastasis, although nomograms may be more accurate in establishing the extent of nodal involvement [148, 191]. The simple Roach formula can also be used [192]. Patients with low- and intermediate-risk PCa may be spared N-staging before potentially curative treatment [126].

Gleason 4 pattern in sextant biopsies can define the risk of N1 disease. Risk of nodal metastases

was 20-45% if any core had a predominant Gleason 4 pattern, or > 3 cores had any Gleason 4 pattern. For the remaining patients, the risk was 2.5%, suggesting that nodal staging is unnecessary in selected patients [193].

5.3.2.2 *Nodal staging using computed tomography (CT) and magnetic resonance imaging (MRI)*

Abdominal CT and MRI indirectly assess nodal invasion by measuring lymph node diameter. Their sensitivity is low and microscopic invasion cannot be detected. Using a 10-mm threshold, CT or MR sensitivity is < 40% [194-206]. Among 4,264 patients, 654 (15.3%) had positive lymph nodes at lymphadenectomy but only 105 (2.5%) had positive CT. Median estimated CT sensitivity, specificity, NPV and PPV were 7%, 100%, 85% and 100%, respectively [205].

Fine-needle aspiration biopsy (FNAB) may be decisive in cases with positive imaging. The lymph nodes can be difficult to reach because of their position. FNAB is not highly sensitive for staging and has a false-negative rate of 40% [207].

For CT or MRI, detection of microscopic lymph node invasion is < 1% in patients with a Gleason score < 8, PSA < 20 ng/mL, or localised disease [202, 208, 209]. CT and MRI should not be used for nodal staging in low-risk patients and reserved for high-risk cancer.

5.3.2.3 *Lymphadenectomy*

The gold standard for N-staging is open or laparoscopic lymphadenectomy. Pelvic lymph node dissection (LND) limited to the obturator fossa will miss ~50% of metastases [210, 211]. When deciding on pelvic LND, extended lymphadenectomy should be considered (Section 7.2.6).

Primary removal of sentinel lymph nodes aims to improve accuracy of detecting tumour bearing nodes while reducing morbidity associated with extended pelvic LND [212, 213]. Image guidance allows intraoperative sentinel node (SN) detection visually [214]. Difficulty in accessing the SN and the lack of large multicenter cohorts are major limitations of this technique. Therefore, for the time being, this remains experimental [215].

5.3.3 *M-staging*

5.3.3.1 *Alkaline phosphatase*

The axial skeleton is involved in 85% of PCa fatalities [216]. The presence and extent of bone metastases accurately reflect prognosis of PCa. Elevated skeletal alkaline phosphatase (ALP) indicates bone metastasis in 70% of cases [217]. Simultaneous measurement of skeletal ALP and PSA increases clinical effectiveness to ~98% [218]. The extent of bone disease is the only variable influencing serum levels of skeletal ALP and PSA, and the former is significantly correlated with extent of bone disease [219].

5.3.3.2 *Bone scan*

Bone scan (BS) has been the most widely used method for evaluating bone metastases of PCa. However, it suffers from relatively low specificity [220]. Thus, in patients with equivocal findings or a small number of hot spots, the metastatic nature of the lesions needs to be checked by other imaging modalities.

The NPV for bone scanning is 87-100% [207, 221-229]. Its diagnostic yield is significantly influenced by the PSA level, the clinical stage and the tumour Gleason score [221-234] and these three factors were the only independent predictors of BS positivity in a study of 853 patients [235]. BS positivity rate is extremely low (< 1%) in low-risk patients [234, 236-238]. In contrast, it is 6.6-38.5% in patients with PSA level of 20-50 ng/mL [221, 224-227, 229, 230, 236-238], 19-90.7% in patients with stage \geq T3 [221, 225, 227, 228, 230, 236] and 16.9-29.6% in patients with Gleason \geq 8 tumours [232, 233, 236, 238]. The proportion of positive BS in patients with PSA level of 10-20 ng/mL (1-33.3%) or Gleason 7 (2.8-22%) is quite variable from one study to another [207, 221, 222, 224-228, 230, 237-239]. In two studies, a major Gleason pattern of 4 was found to be a significant predictor of positive BS [237, 239].

Bone scanning should be performed in symptomatic patients, independent of PSA level, Gleason score or clinical stage [205].

5.3.4 *New imaging modalities*

5.3.4.1 *Nodal metastases*

^{11}C - or ^{18}F -choline positron emission tomography (PET)/CT have good specificity for lymph node metastases, but sensitivity of 10-73% [240, 241].

In a meta-analysis of 609 patients pooled sensitivity and specificity of choline PET/CT for pelvic lymph node metastases were 62% (95% CI, 51-66%) and 92% (95% CI, 89-94%), respectively [242]. In a prospective trial of 75 patients at intermediate risk of nodal involvement (10-35%), the sensitivity was only 8.2% in a region based and 18.9% at a patient-based analysis, too low to be of clinical interest [243]. PET-choline has no place for up-front staging in nodal metastasis. Currently, psmaPET-CT (prostate-specific membrane antigen-PET CT) remains experimental.

MR sensitivity is low for lymph node metastases and similar to that of ¹¹C-choline PET/CT [244, 245]. Ultra-small particles of iron oxide (USPIOs) improve detection of microscopic lymph node metastases on MRI. This approach is cost-effective [246], but is limited by a lack of availability.

5.3.4.2 Bone metastasis

¹⁸F-fluoride PET or PET/CT shows superior sensitivity to bone scanning [240, 247-250]. It remains unclear whether ¹¹C-choline PET/CT is more sensitive than conventional bone scanning, but it has higher specificity, with fewer indeterminate lesions [240, 242, 251].

Diffusion-weighted whole-body and axial MRI are more sensitive than bone scanning and targeted radiography [252-254] in detecting bone metastases in high-risk PCa. Whole-body MRI is also more sensitive and specific than combined bone scan, targeted radiography and abdominopelvic CT [255]. A recent meta-analysis found MRI to be better than choline PET/CT and bone scan for detecting bone metastases on a per-patient basis, although PET/CT had the highest specificity [256].

However, as with PET/CT, the cost-effectiveness of these new MR-based approaches remains to be assessed [257]. Bone scan is therefore preferred on the basis of availability and cost.

5.3.5 Guidelines for staging of prostate cancer

Any risk group staging	LE	GR
Additional imaging is required only if it changes patient management.	2a	A*
For local staging, CT and TRUS should not be used.	3	A
For up-front staging, PET-scanning should not be used.	2a	A

*Upgraded following panel consensus.

Low-risk localised PCa	LE	GR
No additional imaging is recommended for staging purposes.	2a	A

Intermediate-risk PCa	LE	GR
In predominantly Gleason pattern 4, bone scan and cross-sectional imaging is required.	2a	A*

High-risk localised PCa/ High-risk locally advanced PCa	LE	GR
Prostate mpMRI should be used for local staging.	2b	A
CT/MRI and bone-scan should be used in staging.	2b	A
For up-front staging, PET-scanning should not be used.	2a	A

CT = computed tomography; GR = grade of recommendation; LE = level of evidence; mpMRI = multiparametric magnetic resonance imaging; PET = positron emission tomography.

6. DISEASE MANAGEMENT

6.1 Treatment: Deferred treatment (active surveillance/watchful waiting)

6.1.1 Introduction

Many men with localised PCa will not benefit from definitive treatment [258], and ~45% of men with PSA-detected PCa are candidates for deferred management [259]. In men with comorbidity and limited life expectancy, treatment of localised PCa may be deferred to avoid loss of quality of life (QoL). There are two distinct strategies for conservative management that aim to reduce overtreatment: active surveillance and watchful waiting (Table 7.1.1).

6.1.1.1 Definition

6.1.1.1.1 Active surveillance

Active surveillance aims to achieve correct timing for curative treatment, rather than delayed application of palliative treatment [260]. Patients remain under close surveillance, and treatment is prompted by predefined thresholds indicative of potentially life-threatening disease, while considering individual life expectancy.

6.1.1.1.2 Watchful waiting

Watchful waiting (also known as deferred or symptom-guided treatment) arose in the pre-PSA screening era (before 1990). It refers to conservative management, until the development of local or systemic progression with (imminent) disease-related complaints. Patients are then treated palliatively with TURP or other procedures for urinary tract obstruction, and hormonal therapy or radiotherapy for palliation of metastatic lesions. No standardised follow-up is recommended.

Table 6.1.1: Definitions of active surveillance and watchful waiting [261-263]

	Active surveillance	Watchful waiting
Treatment intent	Curative	Palliative
Follow-up	Predefined schedule	Patient-specific
Assessment/markers used	DRE, PSA, re-biopsy, optional MRI	Not predefined
Life expectancy	> 10 years	< 10 years
Aim	Minimise treatment-related toxicity without compromising survival	Minimise treatment-related toxicity
Comments	Only for a subgroup of low-risk patients	Can apply to patients with all stages

6.1.2 **Deferred treatment of localised PCa (stage T1/T2, Nx/N0, M0)**

Clinical stage T1c currently represents 40-50% of new PCa cases [264]. The incidence of small, localised, well-differentiated PCa is increasing, mainly because of PSA screening and multicore biopsy [259]. One clinical trial [265] did not show any difference in 10-year survival between watchful waiting and RP in screen-detected PCa with PSA < 10 ng/mL.

The lead-time in PSA screening is ~10 years [261, 262]. Mortality from untreated, non-screen-detected PCa in patients with Gleason scores of 6 might be only 10% at 20 years follow-up [263].

6.1.2.1 *Active surveillance*

Active surveillance might mean no treatment for patients aged > 70 years, while in younger patients treatment may be delayed for several years. The aim is to reduce overtreatment in patients with clinically confined, very-low-risk PCa, without relinquishing curative treatment, as happens with watchful waiting [260]. Active surveillance is only proposed for highly selected low-risk patients. Current data are from ongoing prospective or retrospective cohorts, without any available randomised clinical trials and the results of active surveillance (AS) are consistent throughout the published cohorts for survival.

One of the largest cohorts with the longest follow-up in a mainly low-risk population includes 993 patients (mean age: 67.8 years) [266]. These men presented with stage T1c or T2a PCa and PSA ≤ 10 ng/mL, age ≤ 70 years and a Gleason score ≤ 6 or age > 70 years with a score of ≤ 7. Initially, six biopsies were performed, but in recent years the 12-core protocol was introduced. After a median follow-up of 6.4 years (21% followed for more than 10 years), the 10- and 15-year OS were 80% and 62%, respectively. At 10 and 15 years, disease-specific survival (DSS) were 98.1% and 94.3% respectively. Twenty-eight men (2.8%) developed metastases during follow-up (all but 2 being Gleason ≥ 7), and 15 died. 63.5% and 55% of men are still alive on active surveillance at 10 and 15 years, respectively. Twenty-seven percent of this cohort eventually underwent radical treatment, prompted by a PSA-DT < 3 years in (43.5%), a Gleason score progression on repeat biopsies (35%) and patient preference (6%).

Several studies have investigated active surveillance in organ-confined disease, the findings of which were summarized in a systematic review including more than 3,900 patients [267]. There is considerable variation between studies regarding patient selection, follow-up policies and when active treatment should be instigated.

Selection criteria discussed in this review suggest: low volume intraprostatic non-aggressive disease: Gleason 6, when specified < 2 - 3 positive cores with < 50% cancer involvement of every positive core, a clinical T1c or T2a, a PSA < 10 ng/mL and a PSA density < 0.15 ng/mL/cc.

A consensus meeting recently suggested also excluding men from AS when any of the following features were present: predominant ductal carcinoma (including pure intraductal carcinoma), sarcomatoid carcinoma, small cell carcinoma, extraprostatic extension or lymphovascular invasion in needle biopsy [269]. Some studies would include men with a PSA < 20 ng/mL, or up to T2b PCa. Even patients with Gleason score 7 (3 + 4) were considered since only 19% of men with a PSA level < 10 ng/mL, PSA-DT < 0.15 ng/mL/g, T1c, and < 2 positive cores, had unfavourable disease at RP [268]. However these criteria are not yet considered as acceptable for AS and should therefore not be used.

A comprehensive review of the currently available patient selection- and follow-up criteria has been published [270], highlighting that repeat-biopsies should be systematically included in an AS policy, even though they are associated with increased erectile dysfunction [271] and infectious complications [272]. Imaging with mpMRI is of particular interest due to its high negative-predictive value for lesion upgrading and for staging anterior prostate lesions [273]. As yet, mpMRI cannot replace follow-up biopsies and should not be used alone as an assessment tool to prompt active treatment [274]. Biological markers, include urine markers such as PCA3, the TMPRSS2: ERG fusion gene or PSA isoforms such as the Phi index appear promising as does genomics on the tissue sample itself [275]. However, further study data will be needed before such markers can be used in standard clinical practice.

Follow up in AS should be based on repeat biopsy, serial PSA measurements and clinical examination (DRE). There is no agreement on which criteria to use as the basis for the decision to proceed to active treatment [276]. Criteria include a change in the Gleason score, the modification of the biopsy results (number of positive cores, increase in the core involvement). These criteria are recognised in all the published cohorts. T- stage increase is also considered. A PSA change (in particular a PSA-DT < 3 years) is often used which is questionable considering the weak link between PSA-DT and grade progression on repeat biopsy [277].

Active treatment may also be instigated upon a patient's request. This occurs in 10-18% of patients on AS [278]. Self-administered questionnaires show that patients experience anxiety and depression during an AS policy, the extent of which, however, does not significantly differ from anxiety reported by men treated by RP [279]. Overall, the discontinuation rate of AS is between 14% to 40% and 40% to 60% at 5 and 10 years, respectively. Depending on the criteria used, CSS at 10 years is reported to be between 96-100%.

Table 6.1.2: Active surveillance in screening-detected PCa

Studies	n	Median follow-up (mo)	pT3 in RP* patients	OS	CSS

* Patients receiving active therapy following initial active surveillance.

CSS = case-specific survival; n = number of patients; OS = overall survival

6.1.2.2 Watchful waiting

The rationale behind watchful waiting is that PCa often progresses slowly, and is predominantly diagnosed in older men with a high incidence of comorbidity and other causes of mortality [286]. Watchful waiting is possible in patients with localised PCa and limited life expectancy, or older patients with less aggressive cancer.

Studies of watchful waiting have included patients with up to 25 years follow-up, with endpoints of OS and DSS. Several series showed a consistent DSS rate of 82-87% at 10 years [287-292], and 80-95% for T1/T2 and Gleason score ≤ 7 [293]. In three studies with data beyond 15 years, the DSS was 80%, 79% and 58% [289, 291, 292], and two reported a 20-year DSS of 57% and 32% [289, 291]. It must be highlighted that the used Gleason classification is not the revised version which is associated with a slight increase in the Gleason classification. Practically, many patients classified as Gleason 6 in older studies would now be classified as Gleason 7. Therefore, the current Gleason 6 population has less aggressive disease compared to the patients classified in the above mentioned cohorts.

Patients with well-, moderately- and poorly differentiated tumours had 10-year CSS of 91%, 90% and 74%,

respectively, correlating with data from the pooled analysis [293].

Observation was most effective in men aged 65-75 years with low-risk PCa [258].

In patients with stage cT1a PCa, 10-year CSS rates were 96% and 94% for grade 1 and 2 tumours, respectively [287]. MFS rate was 92% and 78% for patients with grade 1 and 2 tumours, respectively, indicating a higher risk of progression for moderately differentiated tumours. Similar results were found in other studies of stage cT1a disease [294, 295].

Gleason 6-10 tumours carry a continuously increasing mortality risk for up to 15 years follow-up after watchful waiting [296]. Others have shown that the mortality risk of PCa was high in Gleason 7-10 tumours, intermediate in Gleason 6 tumours, but low in Gleason 2-5 tumours (Table 6.1.4) [297, 298].

Table 6.1.4: 15-year mortality risk for localised PCa in relation to Gleason score in patients aged 55-74 years [297-299]

Gleason score	Cancer mortality risk* (%)	Cancer-specific mortality† (%)
2-4	4-7	8
5	6-11	14
6	18-30	44
7	42-70	76
8-10	60-87	93

* Figures differ among age groups and represent the true risk in the study population (considering actual competing mortality from other causes)

† Figures compensate for differences in competing mortality and indicate outcome if the patient lives for 15 years

Six hundred and ninety-five patients with T1/T2 PCa were randomised to watchful waiting or RP (Table 6.1.5) [299]. Although the study was begun after PSA screening was introduced, only 5% of men were diagnosed by screening. After a median follow-up of 12.8 years, there was a significant decrease in cancer-specific mortality, overall mortality, metastatic progression, and local progression in the RP group vs. watchful waiting.

Table 6.1.5: Outcome of Scandinavian Prostate Cancer Group Study Number 4 at 15 years follow-up [299]

	RP (n = 347) (%)	Watchful waiting (n = 348) (%)	Relative risk (95% CI)	P value
Disease-specific mortality	14.6	20.7	0.62	0.010
Overall mortality	46.1	57.2	0.75 (0.61-0.92)	0.007
Metastatic progression	21.7	33.4	0.59 (0.45-0.79)	< 0.001
Local progression	21.5	49.3	0.34 (0.26-0.45)	NR

CI = confidence interval.

The overall difference was not modified by PSA level (below or above 10 ng/mL) or Gleason score (below or above 7) at diagnosis. Age at randomisation had a profound impact, with a benefit in OS and MFS only in those aged < 65 years.

Another study randomised 731 men with clinically organ-confined PCa (PSA < 50 ng/mL and age < 75 years) to RP or watchful waiting [265]. Half the patients had non-palpable PCa, compared with only 12% in the other trial [299]. Despite a 10-year life expectancy being an inclusion criterion, > 33% of the men died within 10 years, suggesting that the population was less fit than expected, and reduced the ability to assess survival benefit for active treatment [265].

After a mean follow-up of 10 years, there was no significant difference between the treatments for overall mortality (47% for RP vs. 49.9% for the observation group) and PCa-specific survival (5.8% (RP group) vs. 8.4% (observation group)). There were no significant differences in OS when considering patient age, Gleason score, performance status, and Charlson comorbidity index (CCI) score. Only patients with serum PSA > 10 ng/mL or high-risk PCa had a significant OS benefit from RP, with a relative-risk reduction in mortality of 33% and 31%, respectively. There was a relative-risk and absolute-risk reduction of 31% and 10.5%, respectively, for patients with intermediate/high-risk PCa. Patients who underwent RP also had a significant reduction in bone metastases (4.7% vs. 10.6%).

Data from a 1995 study showed a tendency for a higher probability of metastases in the deferred treatment group and shorter CSS was reported after deferred therapy compared with immediate hormone therapy in presumed localised PCa after 15 years of follow-up [300]. Another study showed higher mortality in men with localised PCa treated with 150 mg/day bicalutamide compared with placebo [301].

The data on deferred and conservative management of low-risk disease contrast with the recent increase in the incidence of local treatment from 25 to 34% in the USA in men with life expectancy < 10 years [302]. Swedish data show a higher prevalence of deferred treatment in low-risk disease of 46% [303].

Many small, localised, well-differentiated tumours do not progress, and radical therapy may lead to substantial overtreatment. This was confirmed by a recent analysis at 5 and 10 years in 19,639 patients aged > 65 years who were not given curative treatment. Most men with a CCI score ≥ 2 died from competing causes at 10 years whatever their initial age. However, men without comorbidity or CCI score 1 had a low risk of death at 10 years, especially for well- or moderately differentiated lesions (Table 8.7) [304]. For CCI score ≥ 2 , tumour aggressiveness had little impact on OS, suggesting that patients could have been spared biopsy and diagnosis of cancer. Thus, evaluation of initial comorbidity and survival probability before proposing biopsy or treatment is important [305].

6.1.3 **Deferred treatment for locally advanced PCa (stage T3-T4, Nx-N0, M0)**

The final analysis of the largest RCT focusing on this specific question was published in 2013 [306]. Nine hundred and eighty-five patients with T0-4 N0-2 M0 PCa were treated with androgen-deprivation therapy (ADT) immediately or after symptomatic progression or occurrence of serious complications. After a median follow-up 12.8 years, the OS hazard ratio was 1.21 (95% CI = 1.05-1.39), favouring immediate treatment. The time from randomisation to progression of hormone-refractory disease did not differ significantly, nor did CSS. The median time to start of deferred treatment was 7 years. One hundred and twenty-six patients died without needing treatment (44% of deaths). Immediate ADT resulted in a modest but significant increase in OS, but no significant difference in PCa mortality or symptom-free survival, raising the question of its clinical value. Patients with a baseline PSA > 50 ng/mL had a > 3.5-fold higher mortality risk than those with ≤ 8 ng/mL. If baseline PSA was 8-50 ng/mL, the mortality risk was ~7.5-fold higher in patients with a PSA-DT of < 12 months compared with > 12 months. The time to PSA relapse after response to immediate ADT correlated significantly with baseline PSA.

6.1.4 **Deferred treatment for metastatic PCa (stage M1)**

The only candidates for deferred treatment are asymptomatic patients with a strong wish to avoid treatment-related side-effects. Median survival is ~2 years, therefore, the time without treatment (before symptoms) is short in most cases. The risk of developing symptoms, and even death from PCa, without receiving any benefit from hormone treatment has been highlighted [307, 308]. Patients with deferred treatment for advanced PCa must be amenable to close follow-up.

6.1.5 **Guidelines for active surveillance and watchful waiting**

Recommendations - active surveillance	LE	GR
Patients who are suitable for surgery and radiotherapy must have these options discussed with them.	4	A*
Active surveillance is an option in patients with the lowest risk of cancer progression: > 10 years life expectancy, cT1/2, PSA ≤ 10 ng/mL, biopsy Gleason score ≤ 6 , ≤ 2 positive biopsies, minimal biopsy core involvement ($\leq 50\%$ cancer per biopsy).	2a	A
Follow-up should be based on DRE, PSA and repeat biopsies.		
The optimal follow-up interval is still unclear.	2a	A
Patients should be counselled on the possibility of needing further treatment in the future.	2a	A

Recommendations - watchful waiting for localised prostate cancer	LE	GR
Watchful waiting may be offered to patients not eligible for local curative treatment and those with a short life expectancy	1b	A
During watchful waiting, the decision to start non-curative treatment should be based on symptoms and disease progression (see section 6.1.2.2).		B

Recommendations - watchful waiting for locally advanced prostate cancer	LE	GR
In locally advanced M0 patients unwilling or unable to receive any form of local treatment, a deferred treatment policy using ADT as monotherapy is feasible in asymptomatic patients with a PSA DT > 12 months and a PSA < 50 ng/mL and non-poorly differentiated tumour.	1b	A

**Upgraded following panel consensus.*

ADT = androgen-deprivation therapy; DRE = digital rectal examination; GR = grade of recommendation; LE = level of evidence; PSA = prostate-specific antigen.

6.2 Treatment: Radical prostatectomy

6.2.1 Introduction

The surgical treatment of PCa consists of radical prostatectomy (RP). This involves removal of the entire prostate gland between the urethra and bladder, and resection of both seminal vesicles, along with sufficient surrounding tissue to obtain a negative margin. Often, this procedure is accompanied by bilateral pelvic lymph node dissection. The goal of RP by any approach must be eradication of disease, while preserving continence and whenever possible potency [309]. There is no age threshold for RP and a patient should not be denied this procedure on the grounds of age alone [305]. However, patients with a life expectancy of ≥ 10 years are more likely to benefit from the procedure. Increasing comorbidity greatly increases the risk of dying from non-PCa-related causes [304]. An estimation of life expectancy is paramount in counselling a patient about surgery [310] (see also Section 6.6 - Management of prostate cancer in older men).

Currently, RP is the only treatment for localised PCa to show a benefit for OS and cancer-specific survival (CSS), compared with conservative management, as shown in one prospective randomised trial [311]. During 23.2 years of follow-up, the SPCG-4 trial showed that RP was associated with a reduction of all-cause mortality. The relative risk (RR) of death at 18 years was 0.71 (95% CI, 0.59-0.86). The number needed to treat (NNT) to prevent one death at 18 years of follow-up was 8; the NNT decreased to 4 for men younger than 65 years of age. Radical prostatectomy was also associated with a reduction in PCa-specific mortality at 18 years (RR = 0.56; 95% CI, 0.41-0.77). The benefit of surgery with respect to death from PCa was largest in men younger than 65 years (RR, 0.45) and in those with intermediate-risk PCa (RR, 0.38). However, RP was associated with a reduced risk of metastases among older men (RR, 0.68).

The benefits in OS and CSS were not reproduced in the overall study population (mean age 67 yr) of another prospective randomised trial. After a median follow-up of 10 years, the PIVOT trial showed that RP did not significantly reduce all-cause mortality (hazard ratio (HR) = 0.88; 95% CI, 0.71-1.08) or significantly reduce PCa mortality (HR = 0.63; 95% CI, 0.36-1.09) [265].

- Among men with intermediate-risk tumours, RP significantly reduced all-cause mortality (HR = 0.69; 95% CI, 0.49-0.98).
- Among men with high-risk tumours, RP non-significantly reduced all-cause mortality (HR = 0.40; 95% CI, 0.16-1.00).
- Among men with PSA > 10, RP significantly reduced all-cause mortality (HR = 0.67; 95% CI, 0.48-0.94).

Radical retropubic prostatectomy (RRP) and perineal prostatectomy are performed through open incisions. More recently, minimally invasive laparoscopic radical prostatectomy (LRP) and robot-assisted laparoscopic prostatectomy (RALP) have been developed. RALP is displacing RRP as the gold standard surgical approach for clinically localised PCa in the USA and is being increasingly used in Europe and other parts of the world. This trend has occurred despite the paucity of high-quality evidence to support the superiority of RALP over more-established treatment modalities. A recent systematic review and economic modelling of the relative clinical benefit and cost-effectiveness of laparoscopic and robotic radical prostatectomy demonstrated that robotic surgery had lower perioperative morbidity and a reduced risk of positive surgical margins compared with laparoscopic prostatectomy, although there was considerable uncertainty. There was no evidence of differences in urinary incontinence at 12 months and there was insufficient evidence to draw conclusions on differences in cancer-related, patient-driven or erectile dysfunction outcomes [312]. A recent cohort study demonstrated that RALP and RRP had comparable rates of complications and additional cancer therapies. However, although associated with lower risk of blood transfusions and a slightly shorter length of hospital stay, RALP was associated with a higher probability of experiencing 30- and 90-day genitourinary and miscellaneous medical complications [313].

Surgical expertise has decreased the complication rates of RP and improved cancer cure [314-317]. Lower rates of positive surgical margins for high-volume surgeons suggest that experience and careful attention to surgical details, adjusted for the characteristics of the cancer being treated, can decrease positive surgical margin rates and improve cancer control with RP [318, 319]. More evidence for a volume-outcome relationship was provided by a recent systematic review. There was undeniable evidence suggesting that increased surgeon

volume improves outcomes [320].

The main gap in the evidence base are the lack of direct comparative studies of robotic, laparoscopic and open radical prostatectomy with low risk of bias. Moreover, there is a lack of longer-term outcomes allowing comparison of more certain measures of cancer control, such as cancer-specific mortality and overall mortality [312, 321-325]. Even though there appears to be a clear volume-outcome relationship, suggesting that referral of patients to high-volume centres would seem reasonable, the impact of a shift in practice has yet to be fully determined [320].

6.2.2 **Low-risk prostate cancer**

Patients with low-risk PCa should be informed about the results of two randomised trials comparing retropubic RP vs. watchful waiting (WW) in localised PCa. In the SPCG-4 study, death from any cause (RR 0.57 [95% CI 0.40-0.81]) and distant metastases (RR 0.40; 95% CI, 0.21-0.73) were significantly reduced in low-risk PCa. However, death from PCa [RR 0.54; 95% CI, 0.26-1.13] was not reduced. In the PIVOT trial, a preplanned subgroup analysis of men with low-risk PCa showed that RP did not significantly reduce all-cause mortality (HR 1.15; 95% CI 0.80-1.66), or death from PCa (RR 0.54; 95% CI, 0.26-1.13).

The decision to offer RP in cases of low-risk cancer should be based upon the probabilities of clinical progression, side-effects and potential benefit to survival [326]. It might therefore be reasonable to propose active monitoring to selected patients whose tumours are most likely to be insignificant.

Apart from disease characteristics, age, comorbidities and individual patient preferences impact the choice for surgery vs. active monitoring and should be considered in shared decision making. A recent study assessed the effect of age, health status and patient preferences on outcomes of surgery vs. active surveillance for low risk PCa. As expected, older age and worse baseline health status were associated with a smaller benefit in prostate-cancer-specific mortality and life expectancy with surgery, and increased incremental years with treatment side effects [327].

Pelvic lymph node dissection (eLND) is not necessary in low-risk PCa because the risk for positive lymph nodes does not exceed 5% [328].

6.2.3 **Intermediate-risk, localised prostate cancer**

Patients with intermediate-risk PCa should be informed about the results of two randomised trials comparing RRP vs. WW in localised PCa. In the SPCG-4 study, death from any cause (RR 0.71; 95% CI 0.53-0.95), death from PCa (RR 0.38; 95% CI, 0.23-0.62) and distant metastases (RR 0.49; 95% CI, 0.32-0.74) were significantly reduced in intermediate-risk PCa. In the PIVOT trial, according to a preplanned subgroup analysis among men with intermediate-risk tumours, RP significantly reduced all-cause mortality (HR = 0.69 [95% CI, 0.49-0.98]), but not death from PCa (0.50; 95% CI, 0.21-1.21).

When the tumour is palpable or visible on imaging and clinically confined to the prostate, disease progression can be expected. When managed with non-curative intent, intermediate-risk PCa is associated with 10-year and 15-year prostate-cancer-specific mortality rates of 13 and 19.6%, respectively [329].

The risk of having positive LNs in intermediate-risk PCa is between 3.7-20.1% [328]. An eLND should be performed in intermediate-risk PCa if the estimated risk for positive lymph nodes exceeds 5% [328]. In all other cases, eLND can be omitted, which means accepting a low risk of missing positive nodes. Limited LND should no longer be performed because this misses at least half of the nodes involved [243].

6.2.3.1 *Oncological results of radical prostatectomy in low- and intermediate-risk prostate cancer*

The results achieved in 2 prospective studies involving RP are shown in Table 6.2.1.

Table 6.2.1: Oncological results of radical prostatectomy in organ-confined disease

Study	Year of RP	Median follow-up (mo)	Risk category	12-year CSS (%)	18-year CSS (%)
Bill-Axelson et al, 2014 [311]	1989-1999	160	Low-risk Intermediate-risk	89.8	84.9
Wilt et al, 2012 [265]	1994-2002	120	Low-risk Intermediate-risk	100	94.2

CSS = cancer-specific survival; n = number of patients; PSA = prostate-specific antigen; RP = radical prostatectomy.

6.2.4 **High-risk and locally advanced prostate cancer**

Patients classified with high-risk PCa are at an increased risk of PSA failure, need for secondary therapy, metastatic progression and death from PCa. Nevertheless, not all high-risk PCa patients have a uniformly poor

prognosis after RP [330].

There is no consensus regarding the optimal treatment of men with high-risk PCa. Provided that the tumour is not fixed to the pelvic wall, or that there is no invasion of the urethral sphincter, RP is a reasonable first step in selected patients with a low tumour volume. Extended LND should be performed in all high-risk PCa cases, because the estimated risk for positive lymph nodes is 15-40% [328]. Limited LND should no longer be performed, because it misses at least half the nodes involved [243].

Management decisions should be made after all treatments have been discussed by a multidisciplinary team (including urologists, radiation oncologists, medical oncologists and radiologists), and after the balance of benefits and side effects of each therapy modality has been considered by the patient.

6.2.4.1 *High-risk prostate cancer*

6.2.4.1.1 Gleason score 8-10

Although most poorly differentiated tumours extend outside the prostate, the incidence of organ-confined disease is 26-31%. Patients with high-grade tumours confined to the prostate at histopathological examination have a good prognosis after RP. One of the reasons to opt for surgery is the high rate of downgrading between the biopsy Gleason score and the Gleason score of the resected specimen [331]. These men, in particular, may benefit most from potentially curative resection.

Several retrospective case series have demonstrated good outcomes after RP in the context of a multimodal approach (adjuvant or salvage ADT and/or RT) for patients with a biopsy GS \geq 8. Biochemical PFS (BPFS) at 5- and 10-years follow-up ranged between 35-51% and 24-39%, respectively, while the CSS at 5-, 10- and 15-years follow-up was 96%, 84-88% and 66%, respectively [331-334].

6.2.4.1.2 Prostate-specific antigen > 20 ng/mL

Yossepowitch et al. have reported the results of RP as monotherapy in 275 men with PSA > 20 ng/mL in a cohort with mostly clinically organ-confined tumours and found a PSA failure rate of 44% and 53% at 5 and 10 years, respectively [330]. Thirty-three and 53% of patients with PSA > 20 ng/mL needed secondary treatment at 5 and 10 years, respectively [333]. D'Amico et al. found that men with PSA levels > 20 ng/mL had a 50% risk of PSA failure at 5 years after RP [335]. Spahn et al. published the largest multicentre surgical series to date, including 712 patients with PSA > 20 ng/mL, and reported a CSS of 90% and 85% at 10 and 15 years follow-up, respectively [336].

Reports in patients with a PSA > 20 ng/mL who underwent surgery as initial therapy within a multimodal approach demonstrated a BPFS at 5-, 10- and 15-years follow-up, ranging between 40-63%, 25-48% and 25%, respectively. The CSS at 5, 10 and 15 years ranged between 93-97%, 83-91% and 71-78%, respectively [333-338].

6.2.4.2 *Locally advanced prostate cancer:*

The surgical treatment of clinical stage T3 PCa has traditionally been discouraged [339], mainly because patients have an increased risk of positive surgical margins and lymph node metastases and/or distant relapse [340, 341].

In recent years, however, there has been renewed interest in surgery for locally advanced PCa and several retrospective case series have been published. Although still controversial, it is increasingly evident that surgery has a place in treating locally advanced disease [342-344]. In up to 50% of cases this is part of multi-modality treatment (adjuvant or salvage radiotherapy and/or ADT).

The problem remains the selection of patients before surgery. Nomograms, including PSA level, stage and Gleason score, can be useful in predicting the pathological stage of disease [345, 346]. Radical prostatectomy for clinical T3 cancer requires sufficient surgical expertise to keep the level of morbidity acceptable. It has been shown that continence can be preserved in most cases, and in some cases, potency can also be preserved [347].

Retrospective case series demonstrated 5-, 10- and 15-year biochemical BPFS ranged between 45-62%, 43-51% and 38-49%, respectively. CSS at 5-, 10- and 15-years ranged between 90-99%, 85-92% and 62-84%, respectively. Five- and 10-year OS ranged between 90-96% and 76-77%, respectively [342-344, 346-350].

Only a limited number of cohort studies provided survival data of surgery for cT3b-T4 PCa. In these studies, the CSS was 88-92% at 5 years and 87-92% at 10 years, while the OS was 73-88% at 5 years and 65-71% at 10 years [351-353].

The indication for RP in all previously described stages assumes the absence of clinically detectable nodal involvement. Clinical lymph node-positive (N+) disease will mostly be followed by systemic disease progression. No good evidence exists supporting RP of cN+ patients, therefore local treatment to N+ patients

in a multimodal approach should be discussed with the patients on an individual basis.

6.2.5 Rationale for RP in patients with cN0 but pathologically confirmed lymph node invasion (pN1) PCa

The combination of RP and early adjuvant HT in pN+ PCa has been shown to achieve a 10-year CSS rate of 80% [354, 355]. Furthermore, a retrospective observational study has shown a dramatic improvement in CSS and OS in favour of completed RP vs. abandoned RP in patients who were found to be N+ at the time of surgery. These results suggest that RP may have a survival benefit and the discontinuation of RP in pN+ cases may not be justified [356]. These findings have been corroborated in a contemporary retrospective analysis [357]. This highlights the fact that frozen section is probably useless and should no longer be considered. Radical prostatectomy resulted in superior survival of patients with pN+ PCa after controlling for lymph node tumour burden. The findings from these studies support the role of RP as an important component of multimodal strategies of pN+ PCa.

The incidence of tumour progression is lower in patients with fewer positive lymph nodes [236, 358]. In patients who prove to be pN+ after RP, early adjuvant HT has been shown to significantly improve CSS and OS in a prospective randomised trial. However, this trial included mostly patients with high-volume nodal disease and multiple adverse tumour characteristics. It is unclear whether early adjuvant HT should still be used in the present era of increased detection of microscopic involvement as a result of more frequently performed extended LND. The benefits should be judged against the side effects of long-term HT. Follow-up of PSA and delaying the initiation of HT until rising PSA level is therefore an acceptable option in selected cases with ≤ 2 microscopically involved lymph nodes in an extended nodal dissection. Interestingly, in a retrospective cohort study, maximal local control with RT of the prostatic fossa appeared to be beneficial in PCa patients with pN+ after RP, treated adjuvantly with continuous ADT [359]. The beneficial impact of adjuvant RT on survival in patients with pN1 PCa was highly influenced by tumour characteristics. Men with low-volume nodal disease (≤ 2 lymph nodes) in the presence of intermediate- to high-grade, non-specimen-confined disease and those with intermediate-volume nodal disease (3-4 lymph nodes) represent the ideal candidates for RT after surgery.

Recent studies described survival outcomes after surgery in pN1 PCa, with 5-, 10- and 15-year CSS ranging from 84-95%, 51-86% and 45%, respectively. The OS at 5, 10 and 15 years ranged from 79-85%, 36-69% and 42%, respectively [236, 354-359].

6.2.6 Indication and extent of pelvic lymph node dissection (LND)

It is generally accepted that extended pelvic lymph node dissection (eLND) provides important information for prognosis (number of nodes involved, tumour volume within the lymph node, and capsular perforation of the node), which cannot be matched by any other current procedure [244]. Sentinel node mapping studies have shown that aside from the obturator and external iliac lymph nodes, the prostate also drains to the presacral nodes and most commonly to the internal iliac nodes [243, 360]. Performing eLND results in removal of all lymph nodes in these particular anatomical regions, producing a higher yield of excised lymph nodes compared with a limited LND.

The individual risk of finding positive lymph nodes can be estimated using preoperative nomograms. Only a few of these nomograms are based on extended LND templates. One of those, the Briganti nomogram with the cutoff of 5% as proposed in the EAU Prostate Cancer guidelines, has been externally validated in both open and robot-assisted RP series and showed the highest accuracy when compared with other similar prognostic tools [328, 361, 362].

6.2.6.1 Extent of lymph node dissection

Extended LND includes removal of the nodes overlying the external iliac artery and vein, the nodes within the obturator fossa located cranially and caudally to the obturator nerve, and the nodes medial and lateral to the internal iliac artery. Some lymph node mapping studies have advocated extending the template to include the common iliac lymph nodes up to the ureteric crossing. With this template, 75% of all anatomical landing sites are cleared [360]. A recent prospective mapping study confirmed that a template including the external iliac, obturator and internal iliac areas was able to correctly stage 94% of patients. Nevertheless, in pN+ patients, this template was associated with a 24% incomplete clearance from positive nodes [243]. Adding the common iliac area and the presacral area decreased this risk to only 3%.

It is recommended for each region that the nodes should be sent in separate containers for histopathological analysis, because this will usually be associated with a higher diagnostic gain by the uropathologist.

6.2.6.2 Therapeutic role of extended lymph node dissection (eLND)

Besides being a staging procedure, pelvic eLND may be curative, or at least beneficial, in a subset of patients with limited lymph node metastases [363-366]. In some series, the number of nodes removed during lymphadenectomy has been significantly correlated with time to disease progression [211]. In one population-based study with a 10-year follow-up, patients undergoing excision of at least 10 nodes (node-negative patients) had a lower risk of PCa-specific death at 10 years than those who did not undergo lymphadenectomy [367]. In another series, it was demonstrated that a more extensive LND was associated with improvement in CSS in patients with lymph node invasion [368]. Nevertheless, results from ongoing confirmatory prospective studies are awaited.

6.2.6.3 Morbidity

Pelvic eLND remains a surgical procedure that increases morbidity in the treatment of PCa. When comparing extended vs. limited LND, three-fold higher complication rates have been reported by some authors [369]. Overall complication rates of 19.8% vs. 8.2% were noted for eLND vs. limited LND, respectively, with lymphocoeles (10.3% vs. 4.6%) being the most common. Other authors have reported more acceptable complication rates [370].

Similar rates of lymphocoeles have been observed in RALP series, however, in one subgroup analysis lymphocoeles were more common in the extraperitoneal approach (19%) vs. the transperitoneal approach (0%) [371, 372].

6.2.7 Guidelines for eLND in prostate cancer

	LE	GR
LND is not indicated in low-risk PCa.	2b	A
eLND should be performed in intermediate-risk PCa if the estimated risk for positive lymph nodes exceeds 5%.	2b	B
eLND should be performed in high-risk PCa.	2a	A
Limited LND should not be performed.	2a	A
When nodal involvement is detected after RP:		
• Adjuvant ADT is the standard of care for node-positive (pN+)	1b	A
• Adjuvant ADT with additional radiotherapy may have a role (see Section 6.3.3.3)	2b	B
• Expectant management is optional when the patient has undergone eLND and ≤ 2 nodes show microscopic involvement and a PSA < 0.1 ng/mL and absence of extranodal extension.	2b	B

ADT = androgen deprivation therapy; eLND = extended lymph node dissection; GS = Gleason score; LND = lymph node dissection; PCa = prostate cancer; RP = radical prostatectomy.

6.2.8 Neoadjuvant and adjuvant hormonal therapy and radical prostatectomy

Neoadjuvant hormonal therapy (NHT) is defined as therapy given before definitive local curative treatment. Since PCa is an androgen-dependent tumour, NHT is an appealing concept. A recent review and meta-analysis studied the role of NHT and prostatectomy [373]. NHT significantly reduced positive margin rates (RR = 0.49; $p < 0.00001$), extra-prostatic extension (RR = 1.63; $p < 0.0001$) and lymph node invasion (RR = 0.49; 0.42-0.56; $p < 0.02$). However, this was not associated with improved OS or disease-free survival (DFS).

Regarding adjuvant HT, a Cochrane review has been published [374]: the pooled data showed a non-significant 5-year OS benefit (OR: 1.50 [95% CI: 0.79-2.84]) and no 10-year OS benefit (with again a trend favouring the adjuvant approach). The pooled data for DFS gave an overall OR of 3.73 (95% CI: 2.3-6.03). The overall effect estimate was highly significant ($p < 0.00001$) in favour of the HT arm. The Early Prostate Cancer Trialists' Group (EPC) trial using bicalutamide 150 mg daily [375] could not be included in the Cochrane review due to missing information. After a median follow-up of 7.2 years, there was a significant improvement in objective PFS that was only significant in the locally advanced disease group (HR: 0.75; 95% CI: 0.61-0.91). There was an OS decrease trend in the localised disease group (HR: 1.16; 95% CI: 0.99-1.37). No OS benefit was observed in both localised and locally advanced groups.

The main limitations of the above data are the mixing of pN0 and pN1 populations. For pN+ patients, 2 RCT are available and drive the main conclusion of the Cochrane review, even if non RCT suggest that the benefit might not be so large in all patients [376]. Regarding pN0 / N0 stages, the only RCT is the EPC project [375]. Using more conventional HT, a large retrospective data base with a median follow up of 10 years [377] suggests that adjuvant HT might be linked to an increased specific, but not OS benefit.

6.2.9 Complications and functional outcomes

The intra- and peri-operative complications of retropubic RP and RALP are listed in Table 6.2.2 [378] and see also section 7.8.3 - Radical prostatectomy.

Table 6.2.2: Intra- and peri-operative complications of retropubic RP and RALP (Adapted from [312])

Predicted probability of event	RALP	Laparoscopic RP	RRP
Bladder neck contracture	0.010	0.021	0.049
Anastomotic leak	0.010	0.044	0.033
Infection	0.008	0.011	0.048
Organ injury	0.004	0.029	0.008
Ileus	0.011	0.024	0.009
Deep-vein thrombosis	0.006	0.002	0.014
Predicted rates of event	RALP (%)	Laparoscopic RP (%)	RRP (%)
Clavien I	2.1	4.1	4.2
Clavien II	3.9	7.2	17.5
Clavien IIIa	0.5	2.3	1.8
Clavien IIIb	0.9	3.6	2.5
Clavien IVa	0.6	0.8	2.1
Clavien V	< 0.1	0.2	0.2

RALP = robot-assisted laparoscopic prostatectomy; RP = radical prostatectomy; RRP = radical retropubic prostatectomy.

Post-operative incontinence and erectile dysfunction are common problems following surgery for PCa. A recent systematic review found that the mean continence rates at 12 months were 89-100% for patients treated with RALP and 80-97% for patients treated with retropubic RP [325]. A similar study reported mean potency recovery rates at 12 months of 55-81% for patients treated with RALP and 26-63% for patients treated with retropubic RP [324]. The major limitations of the included studies were the frequent retrospective study design and the use of different assessment tools preventing a proper comparison between techniques and series.

6.2.10 Indications for nerve-sparing surgery

Nerve-sparing RP can be performed safely in most men with localised PCa undergoing RP [379, 380]. In the past decade, a dramatic shift towards lower-stage tumours has become evident. More importantly, men are younger at the time of diagnosis and more interested in preserving sexual function. Nevertheless, clear contraindications are patients in whom there is a high risk of extracapsular disease, such as any cT2c or cT3 PCa, any GS > 7 on biopsy, or more than one biopsy > 6 at the ipsilateral side. Partin tables help to guide decision making [345]. Multiparametric MRI is increasingly being used in the decision-making process to select a nerve-sparing approach [381-383].

If any doubt remains regarding residual tumour, the surgeon should remove the neurovascular bundle (NVB). Alternatively, the use of intra-operative frozen-section analysis can help guide these decisions. This is especially helpful in patients with a palpable lesion close to the capsule during nerve-sparing RP. A wedge of the prostate can then be resected and inked differently. When there is carcinoma extending into the inked margin on frozen-section analysis, the NVB is resected; otherwise, the NVB remains *in situ* [384].

Before surgery the patient must be informed about the potency rates achieved. The patient must be aware that, to ensure adequate cancer control, the nerves may be sacrificed despite any pre-operative optimism suggesting their salvage might be possible.

The early use of phosphodiesterase-5 inhibitors in penile rehabilitation remains controversial. Placebo-controlled prospective studies have shown no benefit from daily early administration of vardenafil or sildenafil vs. on-demand vardenafil or sildenafil in the post-operative period [385, 386]. Conversely, another placebo-controlled prospective study has shown that sildenafil has a significant benefit on the return of normal spontaneous erections [387].

6.2.11 Guidelines for radical prostatectomy

	LE	GR
Patients who are suitable for AS and radiotherapy must have these options discussed with them.	4	A*
In patients with low- and intermediate-risk PCa and a life expectancy > 10 years, RP should be offered.	1b	A
Nerve-sparing surgery may be attempted in pre-operatively potent patients with low risk for extracapsular disease (T1c, GS < 7 and PSA < 10 ng/mL, or refer to Partin tables/nomograms).	2b	B
Multiparametric MRI may help in deciding when to perform nerve-sparing procedures in intermediate- and high-risk disease.	2b	B
In patients with high-risk localised PCa and a life expectancy of > 10 years, RP should be offered in a multimodality setting.	2a	A
In selected patients with locally advanced (cT3a) PCa, and a life expectancy > 10 years, RP may be offered in a multimodality setting.	2b	B
In highly selected patients with locally advanced PCa (cT3b-T4 N0 or any T N1), RP may be offered in a multimodality setting.	3	C
NHT before RP is not recommended.	1a	A
Adjuvant HT for pN0 is not recommended.	1a	A
Adjuvant ADT is the standard of care for node-positive (pN+) patients.	1b	A
In patients who are surgical candidates for radical prostatectomy, all approaches (i.e. open, laparoscopic or robotic) are acceptable because none has clearly shown superiority in terms of functional or oncological results.	1a	A

DFS = disease-free survival; GS = Gleason score; GR = grade of recommendation; LE = level of evidence; MRI = magnetic resonance imaging; NHT = neoadjuvant hormonal therapy; OS = overall survival; PCa = prostate cancer; RP = radical prostatectomy.

6.3 Treatment: definitive radiotherapy

6.3.1 Introduction

There are no published RCT comparing radiotherapy with watchful waiting or active surveillance. The only randomised trial in the modern era is the ProtecT study which has not yet reported its first results. Intensity-modulated radiotherapy (IMRT), with or without image-guided radiotherapy (IGRT), is the gold standard for EBRT. All centres that do not yet offer IMRT should plan to introduce it as a routine method for the definitive treatment of PCa.

Regardless of the technique used, the choice of treatment is multidisciplinary. After the extent of the tumour has been properly assessed, the following are taken into account:

- 2009 TNM classification;
- Gleason score, defined using an adequate number of core biopsies (at least 10);
- Baseline prostate-specific antigen (PSA);
- Age of the patient;
- Patient's comorbidity, life expectancy, and QoL;
- International Prostate Symptom Score (IPSS) and uroflowmetry recordings;
- and the EAU prognostic factor classification.

Additional information on the various aspects of radiotherapy in the treatment of PCa is available in an extensive overview [388].

6.3.2 Technical aspects: three-dimensional conformal radiotherapy (3D-CRT) and intensity-modulated external-beam radiotherapy (IMRT)

Anatomical data is acquired by scanning the patient in a treatment position. The data are transferred to the three-dimensional (3D) treatment planning system, which visualises the clinical target volume and then adds a surrounding safety margin. Real-time verification of the irradiation field using portal imaging allows comparison of the treated and simulated fields, and correction of deviations where displacement is more than 5 mm. Three-dimensional CRT improves local control through dose escalation, without significantly increasing the risk of morbidity.

It is possible to use IMRT with linear accelerators, equipped with the latest multileaf collimators and specific software. At the time of irradiation, a multileaf collimator automatically (and in the case of IMRT continuously) adapts to the contours of the target volume seen by each beam. This allows for a more complex distribution of the dose to be delivered within the treatment field and provides concave isodose curves, which

are particularly useful as a means of sparing the rectum. To date, no randomised trials have been published comparing dose escalation using IMRT and 3D-CRT.

With dose escalation using IMRT, organ movement becomes a critical issue, in terms of both tumour control and treatment toxicity. Evolving techniques will therefore combine IMRT with some form of IGRT, in which organ movement can be visualised and corrected for in real time, although the optimum means of achieving this is still unclear [389]. Tomotherapy is another evolving technique for the delivery of IMRT, which uses a linear accelerator mounted on a ring gantry that rotates as the patient is delivered through the centre of the ring, analogous to spiral CT scanning. Preliminary data suggest that this technique is feasible in PCa treatment [390].

Whatever the techniques and their degree of sophistication, quality assurance plays a major role in the management of radiotherapy, requiring the involvement of physicians, physicists, dosimetrists, radiographers, radiologists and computer scientists.

6.3.3 **Radiotherapy for localised PCa**

6.3.3.1 *Dose escalation*

Several randomised studies (see below) have shown that dose escalation (range 74-80 Gy) has a significant impact on 5-year survival without biochemical relapse [391-397]. These trials have generally included patients from several risk groups, and the use of neoadjuvant/adjuvant hormone therapy (see below) has varied. To date, no trials have shown that dose escalation results in an OS benefit. However, the trials have been remarkably consistent in reporting improvements in freedom from biochemical progression in patients treated with dose-escalated radiotherapy.

In everyday practice, a minimum dose of ≥ 74 Gy is recommended for EBRT + hormone therapy. Currently, it is not possible to make different recommendations according to the patient's risk group.

If IMRT and IGRT are used for dose escalation, severe late side effects \geq grade III for the rectum is about 2-3% and for the genito-urinary tract is 2-5% [393, 394, 424-437] (see also Section 6.8.4.1 Post-treatment quality of life in patients with localised PCa).

Table 6.3.1: Randomised trials on dose escalation in localised prostate cancer

Trial	n	PCa condition	Radiotherapy Dose	Follow-up	Outcome	Results
MD Anderson study 2011 [391]	301	T1-T3, N0, M0, PSA 10 ng/mL vs. PSA > 10 ng/mL	70 vs. 78 Gy	Median 9 years	Disease specific mortality (DSM) vs. other cause of death	High risk / PSA >10 16% DSM @ 70 Gy 4% DSM @ 78 Gy (p = 0.05) Higher risk 15% DSM @ 70 Gy 2% DSM @ 78 Gy (p = 0.03)
PROG 95-09 study [392]	393	T1b-T2b PSA 15 ng/mL 75% GLS < 6	70.2 vs. 79.2 Gy including proton boost 19.8 vs. 28.8 Gy	Median 8.9 years for survivors	10-year ASTRO Biochemical failure (BF)	All patients: 32% BF @ 70.2 Gy 17% BF @ 79.2 Gy (p < 0.0001) Low-risk patients: 28% BF @ 70.2 Gy 7% BF @ 79.2 Gy (p < 0.0001)
MRC RT01 study [388]	843	T1b-T3a, N0, M0 PSA < 50 ng/mL neoadjuvant HT	64 vs. 74 Gy	Median 10 years	Biochemical progression free survival (BFS); OS	43% BFS @ 64 Gy 55% BFS @ 74 Gy (p = 0.0003) 71% OS both groups (p = 0.96)
Dutch randomised phase III trial [394]	664	T1b-T4 143 pts. with (neo)adjuvant HT	68 vs. 78 Gy	Median 51 mo	Freedom from biochemical- or clinical failure (FFF @ 5 years)	54% FFF @ 68 Gy 64% FFF @ 78 Gy (p = 0.02)

French GETUG 06 randomised trial [395]	306	T1b-T3a, N0, M0 PSA < 50 ng/mL	70 vs. 80 Gy	Median 61 mo	Biochemical failure (ASTRO)	39% BF @ 70 Gy 28% BF @ 80 Gy
--	-----	-----------------------------------	--------------	--------------	-----------------------------	----------------------------------

HT = hormone therapy; OS = overall survival.

6.3.3.2 Hypofractionation (HFX)

In radiobiology, the linear quadratic model uses two coefficients, alpha (α) and beta (β) to describe the dose-response relationship. In clinical practice, these coefficients are used to calculate the effect of different fractionation schemes. Fractionated radiotherapy utilises differences in the DNA repair capacity of normal and tumour tissue. In fast growing tissue including many tumours, cells have little time to repair photon-induced DNA damage. The α/β ratio is then typically around 10 Gy. In contrast, tissue with a low cell renewal has a good opportunity for repair between fractions of irradiation. In such tissue, the α/β ratio is 3 Gy or lower. Slowly proliferating cells with low α/β ratios are very sensitive to an increased dose per fraction [398].

While the correct α/β ratio is still controversial, a meta-analysis of 25 studies with > 14,000 patients concludes that PCa due to its slow growth has an α/β ratio of approximately 1.5 Gy. Assuming this value, hypofractionated radiotherapy could be more effective than conventional fractions of 1.8 - 2 Gy [399]. Beyond the radiobiological aspects, hypofractionation HFX can increase the convenience for the patient and lower costs for the health care system.

Several studies report on HFX applied in various techniques and in part also including hormone treatment [400-406]. A systematic review concludes that studies on moderate HFX (2.5 - 4 Gy/fx) delivered with conventional 3D-CRT/IMRT have sufficient follow-up to support the safety of this therapy, but long-term efficacy data are still lacking [407]. Extreme HFX (5-10 Gy/fx) typically requires IGRT and stereotactic body radiotherapy SBRT. Short-term biochemical control is comparable to conventional fractionation. However, there are concerns about high-grade genitourinary and rectal toxicity, and long-term side effects may not all be known, yet [407-409].

Taking into account the published results and the uncertainties of the correct α/β ratio, moderate HFX (Table 6.3.2) plus dose escalation should be done by experienced teams, accompanied by meticulous radiotherapy QA and close attention to organ at risk dose constraints until long-term data are available.

For extreme HFX, it seems prudent to restrict this therapy to prospective clinical trials and to inform patients on the uncertainties of the long-term outcome.

Table 6.3.2: Phase 3 randomised trials of moderate hypofractionation for intact prostate cancer

Study	n	Risk, GS, or NCCN	Regimen	BED, Gy	Median FU, mo	Outcome	Toxicity
Lukka et al. [400]	466	60% GS 6	52.5 Gy/20 fx	62	68	5 yr FFBF 40% (NS)	Gr \geq 3 2% (NS)

BCDF = biochemical or clinical disease failure; BED = biologically equivalent dose, calculated to be equivalent in 2 Gy fractions using an α/β of 1.5 Gy; CI = confidence interval; FFBF = freedom from biochemical failure; FU = follow-up; fx = fractions; GI = gastrointestinal; Gr = grade; GS = Gleason score; GU = genitourinary; HR = hazard ratio; NCCN = National Comprehensive Cancer Network; NS = not significant; n.s. = not stated; ss = statistically significant.

6.3.3.3 Neoadjuvant or adjuvant hormone therapy plus radiotherapy

The combination of radiotherapy with LHRH ADT has definitively proven its superiority compared with radiotherapy alone followed by deferred ADT on relapse, as shown by phase III randomised trials [410-414] (Table 7.3.3). These trials included high risk PCa patients, mostly by virtue of locally advanced (T3-T4 N0-X) disease, though with a wide range of clinical risk factors, such as PSA level or Gleason grade (high risk localised, T1-2, N0-X PCa). The most powerful conclusion from these studies comes from the EORTC 22863 trial, which is the basis for the combination of radiotherapy and ADT in patients with locally advanced PCa as standard practice today.

In daily practice, ADT starts either at the onset of RT (for adjuvant ADT) or 2 or 3 months before (for neoadjuvant), but the concomitant component is crucial to potentiate RT; Long-term ADT, ranging from 2 to 3 years is recommended for locally advanced disease [397, 415] rather than short term (6-months) [414]. Dose escalation phase III randomised trials are going on to assess its impact on DFS. Cardiovascular mortality may be related to ADT, not radiotherapy, as addressed in Section 12.9.3.3.

Whether these results should be applied to patients with intermediate- or high-risk localised PCa is unclear. The Boston trial has shown an improved 8-year OS rate for patients without moderate or severe comorbidity assigned to 6 months of complete ADT (p=0.01) [413], and the RTOG 94-08 study showed an increased 10-year OS rate for intermediate risk only with 4 months of complete ADT (p=0.003) [396].

The EORTC trial 22961 with 970 patients (78% T3-4, 92% N0) combined radiotherapy (70 Gy) with either 6 months or with 3 years of LHRH analogue treatment. With a median follow-up of 6.4 years, both cancer-specific and overall mortality were lower with long-term androgen suppression [397].

In the RTOG 9910 trial, 1,579 intermediate-risk PCa patients were randomised to LHRH antagonist therapy for 8 weeks before radiotherapy (70.2 Gy in 2-D or 3-D techniques) followed by either another 8 or 28 weeks of anti-hormonal treatment. Extended androgen suppression did not significantly improve 10-year rates of distant (both arms 6%), loco-regional (6% vs. 4%) or biochemical progression (both arms 27%), or disease-specific (96% vs. 95%) or OS (66% vs. 67%). The 8+8 week scheme was confirmed as a standard procedure [417].

Table 6.3.3: Studies of use and duration of ADT in combination with RT for prostate cancer

Trial	Year	TNM stage	n	Trial	ADT	RT	Effect on OS
EORTC 22863 [410]	2010	T1-2 poorly differentiated and M0, or T3-4 N0-1 M0	415	EBRT ± ADT	LHRH agonist for 3 yrs (adjuvant)	70 Gy RT	Significant benefit at 10 years for combined treatment (HR 0.60, 95% CI 0.45-0.80, p = 0.0004).
RTOG 85-31 [411]	2005	T3 or N1 M0	977	EBRT ± ADT	Orchiectomy or LHRH agonist 15% radical prostatectomy	65-70 Gy RT	Significant benefit for combined treatment (p = 0.002) seems to be mostly caused by patients with Gleason score 7-10.
Granfors [419]	2006	T3 N0-1 M0	91	EBRT ± ADT	Orchiectomy	65 Gy RT	Significant benefit (p = 0.02 p = 0.03), mainly caused by lymph-node-positive tumours.
D'Amico [413]	2008	T2 N0 M0 (localised unfavourable risk)	206	EBRT ± ADT	LHRH agonist plus flutamide for 6 mo	70 Gy 3D-CRT	Significant benefit (HR 0.55, 95% CI 0.34-0.90, p = 0.01) that may pertain only to men with no or minimal comorbidity.
TROG 96-01 Denham 2011 [414]	2011	T2b-4 N0 M0	802	Neoadjuvant ADT duration	Goserelin plus flutamide 3 or 6 mo before, plus concomitant suppression	66 Gy 3D-CRT	No significant difference in overall survival reported; benefit in prostate-cancer-specific survival (HR 0.56, 95% CI 0.32-0.98, p = 0.04) (10 yrs: HR 0.84, 0.65-1.08; p = 0.18).
RTOG 94-13 [420]	2007	T1c-4 N0-1 M0	1292	ADT timing comparison	2 mo neoadjuvant plus concomitant vs. 4 mo adjuvant suppression	Whole pelvic RT vs. prostate only; 70.2 Gy	No significant difference between neoadjuvant plus concomitant vs. adjuvant androgen suppression therapy groups (interaction suspected).
RTOG 86-10 [412]	2008	T2-4 N0-1	456	EBRT ± ADT	Goserelin plus flutamide 2 mo before, plus concomitant therapy	65-70 Gy RT	No significant difference at 10 years.
RTOG 92-02 [415]	2008	T2c-4 N0-1 M0	1554	Short vs prolonged ADT	LHRH agonist given for 2 years as adjuvant after 4 mo as neoadjuvant	65-70 Gy RT	p = 0.73 p=0.36 overall; significant benefit (p = 0.044) (p = 0.0061) in subset with Gleason score 8-10.
EORTC 22961 [397]	2009	T1c-2ab N1 M0, T2c-4 N0-1 M0	970	Short vs prolonged ADT	LHRH agonist for 6 mo vs. 3 yrs	70 Gy 3D-CRT	Better result with 3-year treatment than with 6 months (3.8% improvement in survival at 5 years).
Pisansky [417]	2014	intermediate risk (94% T1-T2, 6% T3-4)	1579	Short vs prolonged ADT	LHRH antagonist 8+ 8 vs 8+28 weeks	70.2 Gy 2D / 3D	67 vs 68% p = 0.62, confirms 8+8 weeks LHRH as a standard.
SPCGF-7/ SFUO-3 [416]	2009	T1b-2 Grade 2-3, T3 N0 M0	880	ADT ± EBRT	LHRH agonist for 3 mo plus continuous flutamide	70 Gy 3D-CRT vs. no RT	Significantly better survival with combined treatment (HR 0.68, 95% CI 0.52-0.89, p = 0.04).

NCIC CTG PR.3/ MRC PRO7/ SWOG [421]	2015	T3-4 (88%), PSA > 20 ng/mL (64%), GLS 8-10 (36%) N0 M0	1205	ADT ± EBRT	Continuous LHRH agonist	65-70 Gy 3D-CRT vs. no RT	10-years OS = 49% vs 55% favouring combined treatment (HR = 0.7, p < 0.001).
Mottet 2012 [422]	2012	T3-4 N0 M0	273 264	ADT ± EBRT	LHRH agonist for 3 yrs	70 Gy 3D-CRT vs. no RT	Significant reduction of clinical progression; 5-years OS 71.4% vs 71.5%.

LHRH = luteinising-hormone-releasing hormone; RT = radiotherapy; HR = hazard ratio; 3D-CRT = three-dimensional conformal radiotherapy.

6.3.3.4 Neoadjuvant chemotherapy plus radiotherapy

The GETUG 12 trial investigated the impact of neoadjuvant chemotherapy with docetaxel on the PFS in a cohort of 413 high-risk patients, defined as having one or more of the following criteria: T3-4, Gleason score ≥ 8, PSA ≥ 20 ng/mL, pN+. Patients were randomly assigned to either goserelin 10.8 mg every 3 months for 3 years, + four cycles of docetaxel, 70 mg/m² every 3 weeks, + estramustine 10 mg/kg/dL on days 1-5 (arm 1) or to goserelin alone (arm 2). Local therapy was administered at 3 months and consisted of radiotherapy in 358 patients (87%). Toxicity included grade 3-4 neutropenia (27%) with neutropenic fever in 2%, but no toxicity-related death and no secondary leukaemia. A PSA response (PSA < 0.2 ng/mL after 3 months of treatment) was obtained in 34% in the ADT+DE arm and 15% in the ADT arm. With a median follow-up period of 4.6 years, the 4-year PFS was 85% in arm 1 vs. 81% in arm 2 (p = 0.26), but the data need to mature [423].

6.3.3.5 Combined dose-escalated radiotherapy (RT) and androgen-deprivation therapy (ADT)

Zelefsky et al. [438] reported a retrospective analysis comprising 571 patients with low-risk PCa (22.4%), 1074 with intermediate-risk PCa (42.1%), and 906 with high-risk PCa (35.5%). 3D-conformal radiotherapy or IMRT were administered to the prostate and seminal vesicles. The prostate dose ranged from 64.8 to 86.4 Gy; doses beyond 81 Gy were delivered during the last 10 years of the study using image-guided IMRT. Complete androgen blockade with LHRH agonist plus oral antiandrogen was administered at the discretion of the treating physician to 623 high-risk PCa (69%), 456 intermediate-risk PCa (42%) and 170 low-risk PCa (30%) patients. The duration of ADT was 3 months for low-risk patients and 6 months for intermediate-risk and high-risk patients, starting at 3 months before radiotherapy. The 10-year BDFR was significantly improved by dose escalation: 84% (> 75.6 Gy) vs. 70% for low-risk PCa (p = 0.04), 76% (> 81 Gy) vs. 57% for intermediate-risk PCa (p = 0.0001), and 55% (> 81 Gy) vs. 41% for high-risk patients (p = 0.0001). The 6-month ADT also influenced the BDFR in intermediate- and high-risk patients, with 55% for intermediate-risk vs. 36% for high-risk patients (p < 0.0001). In the multivariate analysis, a dose > 81 Gy (p = 0.027) and ADT (p = 0.052) were found to be predictive factors for distant metastasis-free survival, but none of these parameters influenced OS.

6.3.3.6 Recommended external beam radiation therapy (EBRT) treatment policy for localised PCa

6.3.3.6.1 Low-risk PCa

Intensity-modulated radiotherapy with escalated dose and without ADT is an alternative to brachytherapy (see below).

6.3.3.6.2 Intermediate-risk PCa

Patients suitable for ADT can be given combined IMRT with short-term ADT (4-6 months) [396, 439, 440]. For patients unsuitable for ADT (e.g. due to comorbidities) or unwilling to accept ADT (e.g. to preserve their sexual health), the recommended treatment is IMRT at an escalated dose (76-80 Gy) or a combination of IMRT and brachytherapy.

6.3.3.6.3 Localised High-risk PCa

The high risk of relapse outside the irradiated volume makes it mandatory to use a combined modality approach, consisting of dose-escalated IMRT, including the pelvic lymph nodes + long-term ADT. The duration of ADT has to take into account WHO performance status, comorbidities, and the number of poor prognostic factors, including cT stage (> T2c), Gleason score 8-10, and PSA > 20 ng/mL. It is important to recognise that EBRT + short-term ADT did not improve OS in high-risk localised PCa, in the Boston and 04-08 RTOG trials, and long-term ADT is currently recommended for these patients.

6.3.3.6.4 Locally advanced PCa: T3-4 N0, M0

The results of radiotherapy alone are very poor [441]. The randomised trials discussed above have clearly established that the use of ADT produces better outcomes in patients with locally advanced disease who are treated with radiotherapy. Some clinicians have considered that the better outcomes were due to the earlier use

of ADT, and questioned the benefits of radiotherapy itself in this context. However, three trials have established that, in locally advanced disease, radiotherapy is effective and that combined radiotherapy + ADT is clearly superior to ADT alone.

6.3.3.3.6.4.1 MRC PR3/PR07 study - The National Cancer Institute of Canada (NCIC)/UK Medical Research Council (MRC)/Southwest Oncology Group (SWOG) intergroup PR3/PR07 study

This study comprised 1,205 patients, consisting of T3-4 (n = 1057), or T2, PSA > 40 ng/mL (n = 119), or T2, PSA > 20 ng/mL and Gleason score > 8 (n = 25) and T-category unknown (n = 4), who were randomly assigned to lifelong ADT (bilateral orchiectomy or LHRH agonist), with or without radiotherapy (65-70 Gy to the prostate, with or without 45 Gy to the pelvic lymph nodes). After a median follow-up period of 6 years, the addition of radiotherapy to ADT reduced the risk of death from any cause by 23% (p = 0.03) and the risk of death due to PCa by 46% (p = 0.0001) [442, 443].

6.3.3.3.6.4.2 The TAP 32 trial

A total of 273 patients with locally advanced PCa T3-4 or pT3 N0 M0 were randomly assigned to 3 years of ADT using an LHRH agonist (leuporelin), with or without radiotherapy (70 Gy to the prostate plus 48 ± 2 Gy to the pelvic lymph nodes). After a median follow-up period of 67 months, there was a significant improvement in the 5-year disease free survival (p < 0.001), metastatic disease-free survival (p < 0.018), and locoregional PFS (p < 0.0002), but the effect on OS was not reported [422].

6.3.3.3.6.4.3 The SPCG-7/SFUO-3 randomised study [416]

The study compared hormonal treatment alone (i.e. 3 months of continuous androgen blockade followed by continuous flutamide treatment (n = 439) with the same treatment combined with radiotherapy (n = 436). After a median follow-up period of 7.6 years, the 10-year cumulative incidences for PCa specific mortality were 23.9% and 11.9%, respectively (95% CI: 4.9-19.1%), and the 10-year cumulative incidences for overall mortality were 39.4% in the hormonal treatment-only group and 29.6% in the hormonal treatment + radiotherapy group (95% CI: 0.8-18%).

6.3.3.7 Lymph node irradiation

6.3.3.7.1 Prophylactic lymph node irradiation in clinically N0 PCa (estimated cN0)

There is no level 1 evidence for prophylactic whole-pelvic irradiation, since randomised trials have failed to show that patients benefit from prophylactic irradiation (46-50 Gy) of the pelvic lymph nodes in high-risk cases. Such studies include the RTOG 77 06 study (n = 484 with T1b-T2) [441], the Stanford study (n = 91) [444], and the GETUG 01 trial (n = 444 with T1b-T3 N0 pNx M0) [445]. In the RTOG 94-13 study [420], there were no differences in the PFS in patients treated with whole-pelvic or prostate-only radiotherapy, but interactions between whole-pelvic radiotherapy and the duration of ADT were reported following the subgroup analysis.

Pelvic lymphadenectomy may be needed to improve the selection of patients who may be able to benefit from pelvic lymph node irradiation and to supplement the use of Briganti tables [328] and/or the Roach formula [446]. The results of pelvic lymphadenectomy, especially in young patients, allows radiation oncologists to tailor both the planning target volume and the duration of ADT, particularly ensuring that there is no pelvic irradiation for pN0 patients, while it is possible to irradiate, in combination with long-term ADT. The real impact of such an approach remains, so far, hypothetical, since no randomised trials are available. The benefits of pelvic nodal irradiation at a high dosage using IMRT merit further investigation in a phase II trial. One such trial is currently recruiting through the RTOG, and PIVOTAL, a randomised phase II in the UK, has completed accrual.

6.3.3.7.2 Clinical, or pathological node positive, M0 disease

Outcomes in this group after radiotherapy as a sole modality are poor [397], and as a minimum these patients should receive radiotherapy plus long-term ADT. The RTOG 85-31 randomised phase III trial, with a median follow-up period of 6.5 years, showed that 95 of the 173 pN1 patients who received pelvic radiotherapy with immediate hormonal therapy had better 5-year (54%) and 9-year (10%) PFS rates (PSA < 1.5 ng/mL) vs. 33% and 4%, respectively, for radiation alone (p < 0.0001). Multivariate analysis showed that this combination had a statistically significant impact on the OS, disease-specific failure, metastatic failure and biochemical control rates [447]. Evidence concerning the efficacy of pelvic radiotherapy in patients with established lymph node disease is circumstantial. Patients with pelvic lymph node involvement lower than the iliac regional nodes, < 80 years old, with a WHO performance status 0-1 and no severe comorbidity, may be candidates for EBRT + immediate long-term hormonal treatment. Recent data from the UK STAMPEDE trial suggests that pelvic radiotherapy could be beneficial for N1 disease, but this is not based on a randomised comparison [448].

6.3.4 **Proton beam therapy**

In theory, proton beams are an attractive alternative to photon-beam radiotherapy for PCa, as they deposit almost all their radiation dose at the end of the particle's path in tissue (the Bragg peak), in contrast to photons, which deposit radiation along their path. There is also a very sharp fall-off for proton beams beyond their deposition depth, meaning that critical normal tissues beyond this depth could be effectively spared. In contrast, photon beams continue to deposit energy until they leave the body, including an exit dose.

Two recent planning studies comparing conformal proton therapy with IMRT have yielded conflicting results; one study suggested that the two are equivalent in terms of rectal dose sparing, but that IMRT is actually superior in terms of bladder sparing [449]; the other study suggested a clearer advantage for protons [450].

One randomised trial on dose escalation (70.2 vs. 79.2 Gy) has incorporated protons for the boost doses of either 19.8 or 28.8 Gy. This trial shows improved outcome with the higher dose, but it cannot be used as evidence for the superiority of proton therapy per se [392]. Thus, unequivocal information that shows an advantage of protons over IMRT photon therapy is still not available.

Studies from the SEER database, and from Harvard [451, 452], describing toxicity and patient reported outcomes, respectively, do not point to an inherent superiority for protons - indeed, in terms of longer term GI toxicity, proton therapy might even be inferior to IMRT [452].

A retrospective 2:1 matched-control analysis of 27,647 US Medicare patients compared 314 men receiving proton therapy with 628 men who had IMRT. Despite the considerably higher costs for proton therapy, there was some improvement in GU-tract toxicity after 6 months, but not after 12 months, and not at the GI tract [453].

A randomised trial comparing equivalent doses of proton-beam therapy with IMRT is needed to compare the efficacy of protons vs. photons; a study of this type is under consideration by the RTOG. Meanwhile, proton therapy must be regarded as a promising, but experimental, alternative to photon-beam therapy.

6.3.5 **Low-dose rate (LDR) and high-dose rate (HDR) brachytherapy**

6.3.5.1 **LDR brachytherapy**

LDR brachytherapy is a safe and effective technique. There is a consensus on the following eligibility criteria:

- Stage cT1b-T2a N0, M0;
- A Gleason score ≤ 6 assessed on an adequate number of random biopsies;
- An initial PSA level of ≤ 10 ng/mL;
- $\leq 50\%$ of biopsy cores involved with cancer;
- A prostate volume of < 50 cm³;
- An International Prostatic Symptom Score (IPSS) ≤ 12 [454].

Patients with low-risk PCa are the most suitable candidates for LDR brachytherapy. Further guidelines on the technical aspects of brachytherapy have been published recently and are strongly recommended [455]. Outcomes data have been reported for a large population-based cohort in Canada, in which both low- and intermediate-risk patients were treated [456].

There have been no randomised trials comparing brachytherapy with other curative treatment modalities. Outcomes are based on non-randomised case series. The results of permanent implants have been reported from different institutions, with a median follow-up ranging from 36 to 120 months [457]. The recurrence-free survival after 5 and 10 years has been reported to range from 71% to 93% and from 65% to 85%, respectively [458-464]. A significant correlation has been shown between the implanted dose and recurrence rates [465]. Patients receiving a D90 (dose covering 90% of the prostate volume) of > 140 Gy had a significantly higher biochemical control rate (PSA < 1.0 ng/mL) after 4 years than patients who received less than 140 Gy (92% vs 68%). There is no benefit in adding neoadjuvant or adjuvant ADT to LDR salvage brachytherapy [457].

Some patients experience significant urinary complications following implantation, such as urinary retention (1.5-22%), post-implantation transurethral resection of the prostate (TURP), which is required in up to 8.7% of cases, and incontinence (0-19%) [466]. A small randomised trial has suggested that prophylactic tamsulosin does not reduce the rates of acute urinary retention, but may improve urinary morbidity [467]. This observation requires further study in a larger number of patients. Chronic urinary morbidity can occur in up to 20% of patients, depending on the severity of the symptoms before brachytherapy. Previous TURP for benign prostatic hyperplasia increases the risk of post-implantation incontinence and urinary morbidity.

The incidence of grade III toxicity is less than 5%. Erectile dysfunction develops in about 40% of the patients after 3-5 years. In a recent retrospective analysis of 5,621 men who had undergone LDR salvage brachytherapy [468], the urinary, bowel, and erectile morbidity rates were 33.8%, 21%, and 16.7%, respectively, with invasive procedure rates of 10.3%, 0.8%, and 4%, respectively. In patients with permanent

implants, iodine-125 in granular form is the radioactive element of reference, while palladium-103 may be used for less differentiated tumours with a high doubling time. The doses delivered to the planning target volume are 144 Gy for iodine-125 and 125 Gy for palladium-103. A Gleason score of 7 is still a 'grey area', but patients with a Gleason score of 4 + 3 showed no difference in outcome [469].

A small randomised trial has suggested that using stranded rather than loose seeds is associated with better seed retention and less seed migration, and this should be the standard choice [470]. In cases of intermediate- or high-risk localised PCa, brachytherapy + supplemental external irradiation [471] or neoadjuvant hormonal treatment [472] may be considered. The optimum dose of supplemental EBRT is unclear. A randomised trial comparing 44 Gy vs. 20 Gy of EBRT + palladium-103 brachytherapy closed early, showing no difference in the biochemical outcomes [473].

6.3.5.2 HDR brachytherapy

Non-permanent transperineal interstitial prostate brachytherapy using a high-dose-rate iridium-192 stepping source and a remote afterloading technique can be applied with a total dose of 12-20 Gy in two to four fractions, combined with fractionated external radiotherapy of 45 Gy [474]. Higher doses of supplemental EBRT than this may best be delivered with IMRT, as supported by a report from the Memorial Sloan-Kettering Cancer Center indicating that this approach is safe and feasible [475].

Data suggest an equivalent outcome in terms of the BDFS in comparison with high-dose EBRT (HD-EBRT) [476]. In a retrospective analysis of modern series [477, 478], BDFS rates of 85.8%, 80.3% and 67.8% in men with low-risk, intermediate-risk, and high-risk PCa, respectively, were reported after a mean follow-up of 9.43 years. Quality-of-life changes are similar with high-dose EBRT and high-dose-rate (HDR) brachytherapy in terms of diarrhoea and insomnia [479]. However, the frequency of erectile dysfunction was significantly increased with HDR brachytherapy (86% vs 34%). A single randomised trial of EBRT vs. EBRT + HDR brachytherapy has been reported [480]. A total of 220 patients with organ-confined PCa were randomised to EBRT alone with a dose of 55 Gy in 20 fractions, or EBRT with a dose of 35.75 Gy in 13 fractions, followed by HDR brachytherapy with a dose of 17 Gy in two fractions over 24 hours. In comparison with EBRT alone, the combination of EBRT and HDR brachytherapy showed a significant improvement in the BDFR ($p = 0.03$). There were no differences in the rates of late toxicity. Patients randomly assigned to EBRT + brachytherapy had a significantly better QoL as measured by their Functional Assessment of Cancer Therapy-Prostate (FACT-P) score at 12 weeks. However, a very high, uncommon rate of early recurrences was observed in the EBRT arm alone, even after 2 years, possibly due to the uncommon fractionation used [480]. There is still a need to compare dose-escalated EBRT + hormone therapy with the same followed by a brachytherapy boost in intermediate-risk and high-risk patients. A systematic review of non-randomised trials has suggested the possibility that outcomes with EBRT plus HDR brachytherapy are superior to brachytherapy alone, but this needs confirmation in a prospective, randomised trial [481].

For T1-2 N0 M0 disease, the 5-year BDFRs are similar for permanent seed implantation, high-dose (> 72 Gy) external radiation, combination seed/external irradiation, and radical prostatectomy, according to a study of 2991 patients diagnosed with T1-2 consecutive localised PCa treated between 1990 and 1998 at the Cleveland Clinic Foundation and Memorial Sloan-Kettering Cancer Center, with a minimum follow-up period of 1 year [476].

6.3.5.3 Side effects of percutaneous irradiation and brachytherapy

Radiotherapy affects erectile function to a lesser degree than surgery, according to retrospective surveys of patients [482]. A meta-analysis has shown that the 1-year probability rates for maintaining erectile function were 0.76 after brachytherapy, 0.60 after brachytherapy + external irradiation, 0.55 after external irradiation, 0.34 after nerve-sparing RP, and 0.25 after standard RP. When studies with more than 2 years of follow-up were selected (i.e. excluding brachytherapy), the rates became 0.60, 0.52, 0.25, and 0.25, respectively, with a greater spread between the radiation techniques and surgical approaches [483].

Studies have demonstrated a significantly increased risk of developing secondary malignancies of the rectum and bladder following EBRT [484, 485]. In a retrospective evaluation of 30,552 and 55,263 men, who had undergone either EBRT or RP, the risk of being diagnosed with rectal cancer increased by 1.7-fold in comparison with the surgery group [484]. Another analysis [485] showed that the relative risk of developing bladder cancer increased by 2.34-fold in comparison with a healthy control population. On the other hand, a re-analysis of SEER data including more than 100,000 patients, demonstrated a risk of about 0.16% (i.e. 160 cases per 100,000 patients) of radiation-induced malignant tumours [486]. The Memorial Sloan-Kettering Cancer Center group have also reported corresponding data on late toxicity from their experience in 1571 patients with T1-T3 disease treated with either 3D-CRT or IMRT at doses of between 66 Gy and 81 Gy, with a median follow-up of 10 years [487]. Both acute gastrointestinal and genitourinary toxicity appeared to be predictive for corresponding late toxicity. The overall rate of NCIC/Common Toxicity Criteria (CTC) grade 2 or more gastrointestinal toxicity was 5% with IMRT vs. 13% with 3D-CRT. The incidence of grade 2 or higher late

genitourinary toxicity was 20% in patients treated with 81 Gy vs. 12% in patients treated with lower doses. The overall incidences of grade 3 toxicity were 1% for gastrointestinal toxicity and 3% for genitourinary toxicity. These data suggest that IMRT can successfully protect against late gastrointestinal toxicity. Interestingly, with dose escalation, genitourinary toxicity may become the predominant type of morbidity [487].

6.3.6 **Immediate (adjuvant) post-operative external irradiation after RP (cN0 or pN0) (Table 6.3.5)**

Extracapsular invasion (pT3), Gleason score ≥ 7 and positive surgical margins (R1) are associated with a risk of local recurrence, which can be as high as 50% after 5 years [488]. Three prospective randomised trials have assessed the role of immediate post-operative radiotherapy (adjuvant radiotherapy, ART), as follows:

6.3.6.1 *EORTC 22911*

EORTC 22911 [489], with a target sample size of 1005 patients, compared immediate post-operative radiotherapy (60 Gy) with radiotherapy delayed until local recurrence (70 Gy) in patients classified as pT3 pN0 with risk factors R1 and pT2R1 after retropubic RP. Immediate post-operative radiotherapy was well tolerated. Grade 4 toxicity was not observed (Tables 6.8.1 and 6.8.2). The rate of grade 3 genitourinary toxicity was 5.3% vs. 2.5% in the observation group after 10 years. For patients younger than 70 years, the study concluded that immediate post-operative radiotherapy after surgery significantly improved the 10-year biological PFS to 60.6% vs. 41.1% in the observation group. A difference was observed in the clinical progression rates for the entire cohort that favoured ART after 5 years, but this trend was not sustained after 10 years. Locoregional control was better in the long-term follow-up at 10 years after immediate irradiation (hazard ratio (HR) = 0.45; $p < 0.0001$). However, ART patients with pT2-3 R1 also showed an improved clinical PFS after 10 years (HR = 0.69; $p = 0.008$). Overall survival did not differ significantly between the treatment arms. After re-evaluation using a central pathological review, the highest impact of ART was on biochemical progression (HR reduced to 0.3) seen in patients with positive margins, but there was also a positive effect of 10% after 5 years for pT3 with negative margins and other risk factors [490, 491].

6.3.6.2 *ARO trial*

The most suitable candidates for immediate radiotherapy may be those with multifocal positive surgical margins and a Gleason score > 7 . The conclusions of ARO trial 96-02 ($n = 385$) appear to support those of the EORTC study. After a median follow-up period of 112 months, the radiotherapy group demonstrated a significant improvement in BDFR of 56% vs. 35%, respectively ($p = 0.0001$). However, unlike other studies, and of major interest, the randomization of patients was carried out after they had achieved an undetectable PSA level following RP (< 0.1 ng/mL) and only pT3 tumours were included. This result indicates that ART is effective, even in the setting of an undetectable PSA after RP and additional risk factors [491].

6.3.6.3 *SWOG 8794 trial*

Conversely, the updated results, with a median follow-up of more than 12 years, of the SWOG 8794 trial, which randomly assigned 425 pT3 patients, showed that adjuvant radiation significantly improved the metastasis-free survival, with a 10-year metastasis-free survival of 71% vs. 61% (median prolongation of 1.8 years, $p = 0.016$) and a 10-year OS of 74% vs. 66% (median: 1.9 years prolongation; $p = 0.023$) [492].

6.3.6.4 *Conclusion*

Thus, for patients classified as pT3 pN0 with a high risk of local failure after RP due to positive margins (highest impact), capsule rupture, and/or invasion of the seminal vesicles, who present with a PSA level of < 0.1 ng/mL, two options can be offered in the framework of informed consent. These are:

- Immediate ART to the surgical bed [489, 491, 493] after recovery of urinary function;
or
- Clinical and biological monitoring followed by salvage radiotherapy (SRT) before the PSA exceeds 0.5 ng/mL [494, 495] (see Section 6.10.5.1).

Table 6.3.4: Overview of all three randomised trials for adjuvant radiation therapy after RP

Reference	n	Inclusion criteria	Randomization	Definition of BCR PSA (ng/mL)	Median follow-up (mo)	Biochemical Progression-free survival (bNED)	Overall survival
SWOG 8794 [493]	431	pT3 cN0 ± involved SM	60-64 Gy vs observation	> 0.4	152	10 years: 53% vs 30% (p < 0.05)	10 years: 74% vs 66% Median time: 15.2 vs 13.3 years p = 0.023
EORTC 22911 [489]	1005	pT3 ± involved SM pN0 pT2 involved SM pN0	60 Gy vs observation	> 0.2	127	10 years: 60.6% vs 41% (p < 0.001)	81% vs 77% NS
ARO 96-02 [491]	388	pT3 (± involved SM) pN0 PSA post-RP undetectable	60 Gy vs observation	> 0.05 + confirmation	112	10 years: 56% vs 35% (p = 0.0001)	10 years: 82% vs 86% n.s.

BCR = biochemical recurrence; NS = not significant; PSA = prostate-specific antigen; RP = radical prostatectomy; SM = surgical margin.

see Section 6.10.5.1 for delayed (salvage) post-radical prostatectomy external irradiation.

6.3.7 **Immediate (adjuvant) post-operative external irradiation after radical prostatectomy (RP) (pN1)**

In a retrospective matched-pair analysis with 364 pN+ patients, men who received adjuvant RT in addition to androgen deprivation therapy after radical prostatectomy had a 16% better 10-year cancer specific survival as compared to those without ADT [496]. In a recent study comparing lymph node positive prostatectomy patients who received either adjuvant ADT alone (n = 721) or ADT+ART (n = 386), the multimodal treatment reduced 8-year cancer-specific mortality (7.6% vs 13.8%, p = 0.08) [359]. Subgroup analysis in this retrospective study demonstrated a significant benefit from additional ART for patients with intermediate risk (1-2 positive nodes, GLS 7-10 and pT3b/4 or positive surgical margins; 6.9% vs 15.8%, p = 0.03) and for patients with high risk (3-4 positive nodes irrespective of further risk parameters; 3.5% vs 21.2%, p = 0.02). The results could be confirmed with the end-point OS. These data need prospective validation, but could be helpful in individual decision making.

6.3.8 **Conclusion and Guidelines for definitive radiotherapy**

Statement	LE
The highest effect of adjuvant radiotherapy is seen in patients with pT3R1 PCa.	1a

	LE	GR
Patients who are suitable for AS and surgery must have these options discussed with them.	4	A
EBRT should be offered in all risk groups of non-metastatic PCa.	2a	A
In low-risk PCa, the total dose should be 74 to 78 Gy.	1a	A
In patients with low-risk PCa, without a previous TURP and with a good IPSS and a prostate volume < 50 mL, LDR brachytherapy is a treatment option.	2a	A
In intermediate-risk PCa the total dose should be 76-78 Gy, in combination with short-term ADT (4-6 mo).	1b	A
In patients with high-risk localised PCa, a total dose of 76-78 Gy in combination with long-term ADT (2-3 yr) is recommended.	1b	A
In patients with locally advanced cN0 PCa, radiotherapy must be given in combination with long-term ADT (2-3 yr).	1a	A
IMRT is the recommended modality for definitive treatment of PCa by EBRT.	2a	A
In patients with cN+ PCa, pelvic external irradiation can be given in combination with immediate long-term ADT.	2b	B
In patients with pT3,N0M0 PCa and an undetectable PSA following RP, adjuvant external beam irradiation has to be discussed as an option because it improves at least biochemical-free survival	1a	A
Patients with pT3,N0M0 PCa and an undetectable PSA following RP should be informed about salvage irradiation as an alternative to adjuvant irradiation when PSA increases (see Section 6.10.5.1).	2b	A

ADT = androgen deprivation therapy; CRT = conformal radiotherapy; EBRT = external-beam radiation therapy; GR = grade of recommendation; IMRT = intensity-modulated radiotherapy; LE = level of evidence; PCa = prostate cancer; PSA = prostate-specific antigen; TURP = transurethral resection of prostate; WHO = World Health Organization.

6.4 Treatment: Options other than surgery and radiotherapy for the primary treatment of localised prostate cancer

6.4.1 Background

Besides radical prostatectomy (RP), external-beam radiation and brachytherapy, other modalities have emerged as therapeutic options in patients with clinically localised PCa [497-500]. In this chapter, we will consider both whole gland and focal treatment, looking particularly at high-intensity focused ultrasound (HIFU) and cryosurgery (CSAP) as sufficient data are available to form the basis of some initial judgements on these latest additions to the management of PCa.

Other options - such as photodynamic therapy, radiofrequency ablation and electroporation, among others - are considered to be in the early phases of evaluation and will therefore not be discussed in this edition of the guidelines.

Both HIFU and CSAP have been developed as minimally invasive procedures with the aim of equivalent oncological safety with reduced toxicity.

6.4.2 Cryosurgery

Cryosurgery uses freezing techniques to induce cell death by:

- dehydration resulting in protein denaturation;
- direct rupture of cellular membranes by ice crystals;
- vascular stasis and microthrombi, resulting in stagnation of the microcirculation with consecutive ischaemic apoptosis [497-500].

Freezing of the prostate is ensured by the placement of 12-15 x 17 gauge cryoneedles under transrectal ultrasound (TRUS) guidance, placement of thermosensors at the level of the external sphincter and bladder neck, and insertion of a urethral warmer. Two freeze-thaw cycles are used under TRUS guidance, resulting in a temperature of -40°C in the mid-gland and at the neurovascular bundle. Currently, the so-called third-generation cryosurgery devices are mainly used.

6.4.2.1 Indication for cryosurgery

Patients who are potential candidates for CSAP are those who have organ-confined PCa and those identified as having minimal tumour extension beyond the prostate [497-499]. The prostate should be < 40 mL in size. Prostate glands > 40 mL should be hormonally downsized to avoid any technical difficulty in placing cryoprobe under the pubic arch. Prostate-specific antigen (PSA) serum levels should be < 20 ng/mL, and the

biopsy Gleason score should be ≤ 7 . Potential candidates for CSAP are:

- patients with low-risk PCa, or intermediate-risk PCa whose condition prohibits radiotherapy or surgery;
- at the time of therapy, the size of the prostate should be < 40 mL; volume reduction may be achieved by androgen ablation.

It is important that patients with a life expectancy > 10 years should be fully informed that there are limited data on the long-term outcome for cancer control at 10 and 15 years.

6.4.2.2 *Results of modern cryosurgery for PCa*

The therapeutic results of cryotherapy have improved over time with the introduction of enhanced techniques such as gas-driven probes and transperineal probe placement, as used in third-generation cryosurgery [501-506].

An objective assessment of PSA outcome is not easily performed because some institutions use PSA values < 0.1 ng/mL as an indicator of therapeutic success, whereas others use the old American Society of Therapeutic Radiology and Oncology (ASTRO) criteria, which require three initial consecutive increases in PSA level.

With regard to second-generation CSAP, if a PSA nadir < 0.5 ng/mL is used, BDFS at five years is 60% and 36% for low-risk and high-risk patients, respectively [501, 502].

Long et al. [501] have performed a retrospective analysis of the multicentre, pooled, CSAP results of 975 patients stratified into three risk groups. Using PSA thresholds of 1.0 ng/mL and < 0.5 ng/mL at a mean follow-up of 24 months, the five-year actuarial BDFS rate was:

- 76% and 60%, respectively, for the low-risk group
- 71% and 45%, respectively, for the intermediate-risk group
- 61% and 36%, respectively, for the high-risk group.

According to a recent meta-analysis of 566 cryosurgery-related publications, there were no controlled trials, survival data or validated biochemical surrogate end-points available for analysis [507].

Cryosurgery showed progression-free survival (PFS) of 36-92% (projected one- to seven-year data), depending on risk groups and the definition of failure. Negative biopsies were seen in 72-87% of cases, but no biopsy data were available for the currently used third-generation cryotherapy machines.

With regard to third-generation cryosurgery, clinical follow-up is short, with a 12-month PSA follow-up carried out in only 110/176 (63%) patients [501-506]. Eighty of these (73%) patients still had a PSA nadir < 0.4 ng/mL, whereas 42/65 (64.6%) low-risk patients remained free from biochemical progression using the 0.4 ng/mL cut-off.

Longer follow-up has been reported by Bahn et al. [504], who have analysed the therapeutic results of 590 patients undergoing CSAP for clinically localised and locally advanced PCa. At a PSA cut-off level of < 0.5 ng/mL, the seven-year BDFS for low-, medium- and high-risk groups was 61%, 68% and 61%, respectively. PSA nadir levels in 2,427 patients registered in the Cryo On-Line Data (COLD) Registry showed that a PSA nadir of 0.6 ng/mL or above was associated with significant risks of biochemical failure (29.5%, 46% and 54% in low-, intermediate- and high-risk groups, respectively) within the first two years [508].

In a randomized comparison between whole-gland cryotherapy and external-beam radiotherapy, no difference in 36 months of disease progression was observed at 100 months follow-up [509]. Men in both arms of the study received three to six months of neoadjuvant androgen ablative therapy.

6.4.2.3 *Complications of cryosurgery for primary treatment of PCa*

Erectile dysfunction occurs in about 80% of patients and this remains a consistent complication of the CSAP procedure, independent of the generation of the system used [510]. The complication rates described in third-generation cryosurgery include tissue sloughing in about 3%, incontinence in 4.4%, pelvic pain in 1.4% and urinary retention in about 2% [501-506]. The development of fistula is usually rare, being $< 0.2\%$ in modern series. About 5% of all patients require transurethral resection of the prostate (TURP) for subvesical obstruction.

6.4.3 *High-intensity focused ultrasound of the prostate*

HIFU consists of focused ultrasound waves, emitted from a transducer, that cause tissue damage by mechanical and thermal effects as well as by cavitation [511]. The goal of HIFU is to heat malignant tissues above 65°C so that they are destroyed by coagulative necrosis.

HIFU is performed under general or spinal anaesthesia, with the patient lying in the lateral position.

The procedure is time-consuming, with about 10 g prostate tissue treated per hour. In a 2006 review, 150 papers related to HIFU were identified and evaluated with regard to various oncological and functional outcome parameters [507]. No controlled trial was available for analysis, and no survival data were presented. No validated biochemical, surrogate end-point was available for HIFU therapy. Potential candidates are patients with low to moderate risk in investigational settings. The patient should be informed about the lack of long-term outcome data at > 10 years (see 7.4.4.2).

6.4.3.1 Results of high-intensity focused ultrasound in PCa

As with CSAP, various PSA thresholds are defined for biochemical cure, and no international consensus exists on objective response criteria. The Stuttgart criteria ($> \text{PSA nadir} + 1.2 \text{ ng/mL}$) have been proposed to define BCR after HIFU treatment [512]. As a consequence of the lower PSA cut-off for recurrence than in the Phoenix criteria ($\text{PSA nadir} + 2 \text{ ng/mL}$), the outcome may be approximately 10% lower using the Stuttgart criteria than the Phoenix criteria [513]. According to the review mentioned above [507], HIFU showed PFS (based on PSA \pm biopsy data) of 63-87% (projected three- to five-year data), but median follow-up in the studies ranged from 12-24 months only.

In one of the largest single-centre studies, 227 patients with clinically organ-confined PCa were treated with HIFU, and their outcome data were analysed after a mean follow-up of 27 months (range: 12-121 months) [514] (see Table 6.4.1). The projected five-year BDFS was 66%, or only 57% if patients had exhibited a pre-therapeutic PSA value of 4-10 ng/mL. Incontinence and bladder neck stricture decreased over time from 28% and 31%, respectively, to 9% and 6%, respectively. In another study [515], a significant decrease in pre-treatment PSA serum levels from 12 ng/mL to 2.4 ng/mL was observed. However, 50% of the 14 patients demonstrated positive prostate biopsies during follow-up. In a third study [516], a complete response rate (i.e. $\text{PSA} < 4 \text{ ng/mL}$) and six negative biopsies were achieved in 56% of the patients.

From a single centre, the eight-year BDFS rates (Phoenix definition) were 76%, 63%, and 57% for low-, intermediate-, and high-risk patients, respectively ($p < 0.001$) after whole-gland treatment. At 10 years, the PCa-specific survival rate and metastasis-free survival rate (MFSR) were 97% and 94%, respectively [517].

Thüroff et al. [516] have summarised the efficacy results of a European multicentre study comprising the data of 559 patients with mainly low- and intermediate-risk PCa, and have reported a negative biopsy rate of 87.2% in 288 men with a follow-up of at least six months. A PSA nadir after six months' follow-up could be determined in 212 patients, and was 1.8 ng/mL. However, following the initial procedure, it could be demonstrated that the PSA nadir might be reached in 12-18 months.

Blana et al. have reported the results of 146 patients undergoing HIFU with a mean follow-up of 22.5 months [518]. The mean PSA level before treatment was 7.6 ng/mL; the PSA nadir achieved after three months was 0.07 ng/mL. However, after 22 months, the median PSA level was 0.15 ng/mL. Of the 137 men available for analysis, 93.4% demonstrated a negative control biopsy. The PSA nadir appeared to be strongly associated with treatment failure [519] ($p < 0.001$). Patients with a PSA nadir of 0.0-0.2 ng/mL had a treatment failure rate of only 11% compared with 46% in patients with a PSA nadir of 0.21-1.00 ng/mL, and 48% with a PSA nadir of $> 1.0 \text{ ng/mL}$. Recently, the group has updated its results, with a total of 163 men treated for clinically organ-confined PCa. Within the 4.8 ± 1.2 years of follow-up, the actuarial DFS rate at five years was 66%, with salvage treatment initiated in 12% of patients [520].

In another study, 517 men with organ-confined or locally advanced PCa were treated with HIFU [521]. Biochemical failure was defined as the $\text{PSA nadir} + 2 \text{ ng/mL}$, according to the Phoenix guidelines with regard to radiotherapy. After a median follow-up of 24 months, the BDFS was 72% for the entire cohort. The BDFS in patients with stage T1c, T2a, T2b, T2c and T3 groups at five years was 74%, 79%, 72%, 24% and 33%, respectively ($p < 0.0001$). The BDFS in patients in the low-, intermediate- and high-risk groups at five years was 84%, 64% and 45%, respectively ($p < 0.0001$). The BDFS in patients treated with or without neoadjuvant hormonal therapy at seven years was 73% and 53% ($p < 0.0001$), respectively. Post-operative erectile dysfunction was noted in 33 out of 114 (28.9%) patients who were pre-operatively potent.

In a retrospective study, 137 patients with PCa underwent HIFU [522]. After a median follow-up of 36 months, 22% of the patients relapsed according to the Phoenix criteria. The five-year DFS rate was 78% based on these criteria, and 91%, 81% and 62% in the low-, intermediate- and high-risk groups, respectively. Urge incontinence (16 cases) and dysuria (33 cases) occurred after removal of the urethral catheter in 11.8% and 24.1%, respectively.

To evaluate whether the location (apex/mid-gland/base) of PCa influences the risk of incomplete transrectal HIFU ablation, Boutier et al. [523] analysed 99 patients who underwent PCa HIFU ablation (Ablatherm; EDAP, Vaulx-en-Velin, France) with a 6 mm safety margin at the apex, and had systematic biopsies at three to six months after treatment. Residual cancer was found in 36 patients (36.4%) and 50 sextants (8.4%); 30 (60%) positive sextants were in the apex, 12 (24%) in the mid-gland, and eight (16%) in the base. Statistical analysis showed that the mean (95% CI) probability for a sextant to remain positive after HIFU ablation was 8.8% (3.5-20.3%) in the base, 12.7% (5.8-25.9%) in the mid-gland, and 41.7% (27.2-57.89%)

in the apex. When a 6 mm apical safety margin was used, treatment-associated side-effects, especially incontinence and erectile dysfunction, were fewer, but residual cancer after HIFU ablation was significantly more frequent in the apex.

Komura et al. [524] have analysed the oncological outcome in 144 patients with T1/T2 PCa and a median follow-up of 47 (2-70) months. Thirty-nine percent of patients relapsed and approximately 40% developed a clinical or subclinical urethral stricture post-operatively. Most interestingly, the five-year DFS was significantly better in those with a stricture than in those without (78.2% vs 47.8%, $p < 0.001$), indicating the need for more aggressive treatment, especially at the apex of the prostate. Crouzet et al. [517] published the results of 1,002 men treated with whole-gland HIFU with a median follow-up of 6.4 years. PCa-specific survival and metastasis-free survival at 10 years were 97% and 94%, respectively. Overall, 37.1% of men received any form of salvage treatment.

Table 6.4.1: Summary of studies addressing HIFU in PCa

Study (reference no.)	n	Median follow-up	Outcome measure
Blana et al. 2004 [518]	137	22.5 mo	87% PSA < 1 at follow-up
Poissonnier et al. 2007 [514]	227	27 mo	66% BCR-free at 5 y
Crouzet et al. 2013 [517]	1,002	6.4 y	76%, 63% and 57% BCR-free (Phoenix) for low-, intermediate- and high-risk disease, respectively DFS at 10 y: 97%; metastasis-free: 94%
Thüroff et al. 2003 [516]	559	6 mo	87% biopsy negative at 6 mo
Uchida et al. 2009 [521]	517	24 mo	72% BCR-free (Phoenix)
Inoue et al. 2011 [522]	137	36 mo	78% BCR-free (Phoenix)
Boutier et al. 2011 [523]	99	6 mo	64% biopsy tumour-free
Komura et al. 2011 [524]	144	47 mo	61% BCR-free (Phoenix)
Thüroff and Chaussy 2013 [525]	704	5.3 y	60%, BCR-free (Phoenix) at 10 y 99% DFS at 10 y; 95% metastasis-free at 10 y
Pfeiffer et al. 2012 [526]	191	53 mo	85%, 65% and 55% biochemical-free survival rate (Stuttgart) for low-, intermediate- and high-risk disease, respectively
Pinthus et al. 2012 [527]	402	24 mo	68% BCR-free (Stuttgart) at 4 y

BCR = biochemical recurrence; DFS = disease-free survival; n = number of patients; PSA = prostate-specific antigen.

6.4.4 Focal therapy of PCa

During the past two decades, there has been a trend towards earlier diagnosis of PCa as a result of greater public and professional awareness, leading to the adoption of both formal and informal screening strategies. The effect of this has been to identify men at an earlier stage with smaller tumours that occupy only 5-10% of the prostate volume, with a greater propensity for unifocal or unilateral disease [528-530].

Most focal therapies to date have been achieved with ablative technologies: cryotherapy, HIFU or photodynamic therapy, electroporation, focal radiotherapy by brachytherapy, or CyberKnife Robotic Radiosurgery System technology (Accuray Inc., Sunnyvale, CA, USA). The main purpose of focal therapy is to limit treatment toxicity in patients that could benefit from local disease control [531-533].

6.4.4.1 Pre-therapeutic assessment of patients

The high number of random and systematic errors associated with TRUS-guided random biopsy regimens means that this procedure is not sufficiently accurate for selecting candidates for focal therapy. Perineal biopsy or magnetic resonance imaging (MRI) may be useful tools. For characterizing men considering focal therapy, transperineal prostate biopsy using a template-guided approach is recommended [534-536]. When used with a 5 mm sampling frame, this approach can rule in or out PCa foci with volumes of 0.5 mL and 0.2 mL with 90% certainty [537]. Thus, the exact anatomical localization of the index lesion - defined as the biologically most aggressive - can be accurately determined.

6.4.4.2 Patient selection for focal therapy

The primary objective of treatment must be the eradication of measurable and biologically aggressive disease with minimal toxicity. However, although treatment is usually intended to be a single session, patients should know that further treatment might be necessary in the future. Standardised follow-up schedules and retreatment indications are currently non-existent. Based on published data, the following criteria identify

possible candidates for currently ongoing trials of focal treatment:

- candidates for focal therapy should ideally undergo transperineal template mapping biopsies; multiparametric MRI with or without TRUS biopsy may be an option in the hands of experts;
- focal therapy should be limited to patients with a low to moderate risk in investigational settings; retrospective data have shown the presence of grade I-III toxicity in 13% of cases [538];
- patients should be counselled with caution as no data on functional and oncological outcomes are available;
- patients must be informed that:
 1. the therapy is investigational;
 2. the long-term consequences are unknown;
 3. the optimal method for follow-up and the criteria for salvage therapy are not clear;
 4. focal therapy is not without toxicity.

Early reports suggest the feasibility of MRI-guided focal salvage cryotherapy after local radiotherapy [539] and focal electroporation [540].

6.4.5 **Conclusions and guidelines for experimental therapeutic options to treat clinically localised PCa**

Conclusions	LE
HIFU has been shown to have a therapeutic effect in low-stage PCa, but prospective randomised comparison studies are not available.	3
Cryotherapy for PCa compares unfavourably with external-beam radiation for the preservation of sexual function.	2
PSA nadir values after ablative therapies may have prognostic value.	3
Focal therapy of any sort is investigational, and the follow-up and retreatment criteria are unclear.	3
HIFU treatment for localised PCa results in mild to moderate urine incontinence in less than 20% of men.	

Recommendations	GR
In patients who are unfit for surgery or radiotherapy, CSAP can be an alternative treatment for PCa.	C
If HIFU is offered, the lack of long-term comparative outcome data (> 10 y) should be discussed with the patient.	C
Focal therapy of PCa is still in its infancy and cannot be recommended as a therapeutic alternative outside clinical trials.	A

CSAP = cryosurgery; GR = grade of recommendation; HIFU = high-intensity focused ultrasound; LE = level of evidence; PSA = prostate specific antigen.

6.5 **Treatment: Hormonal therapy - rationale and available drugs**

6.5.1 **Introduction**

6.5.1.2 *Different types of hormonal therapy*

ADT can be achieved by either suppressing the secretion of testicular androgens or inhibiting the action of circulating androgens at the level of their receptor using competing compounds known as anti-androgens. In addition, these two methods can be combined to achieve what is known as complete (or maximal or total) androgen blockade (CAB) [541].

6.5.2 **Testosterone-lowering therapy (castration)**

6.5.2.1 *Castration level*

Surgical castration is still considered the 'gold standard' for ADT, against which all other treatments are rated. It leads to a considerable decline in testosterone levels and induces a hypogonadal status, known as the 'castration level'.

The standard castrate level was < 50 ng/dL (1.7 nmol/L). It was defined more than 40 years ago, when testosterone level testing was limited. Current testing methods have found that the mean value of testosterone after surgical castration is 15 ng/dL [542]. This has led to a revisiting of the current definition of castration, with a more appropriate level defined as below 20 ng/dL (1 nmol/L). This new definition is important as better results are repeatedly observed with levels around or below 1 nmol/L compared to 1.7 nmol/L [543-545]. However, the castrate level considered by the regulatory authorities is still 50 ng/dL (1.7 nmol/L), which is

also the threshold that has been used in all clinical trials addressing castration in PCa patients.

6.5.2.2 *Bilateral orchiectomy*

Bilateral orchiectomy, either total or subcapsular pulpectomy, is a simple, cheap and virtually complication-free surgical procedure. It is easily performed under local anaesthesia [546] and is the quickest way to achieve a castration level, usually within less than 12 hours. It is irreversible and does not allow for intermittent treatment.

6.5.3 *Oestrogens*

Opposed to castration, oestrogens resultant testosterone suppression is not associated with bone loss [547].

6.5.3.1 *Diethylstilboesterol (DES)*

Early studies by the Veterans Administration (VACURG) tested oral Diethylstilboesterol (DES) at 5 mg/day. This dosage was associated with high cardiovascular morbidity and mortality, which was secondary to first-pass hepatic metabolism and the formation of thrombogenic metabolites. Lower doses of 1 mg/day and 3 mg/day were found to be as effective as bilateral orchiectomy [548], with still more side effects compared to castration.

6.5.3.2 *Strategies to counteract the cardiotoxicity of oestrogen therapy*

Two strategies have been attempted to neutralise oestrogen cardiotoxicity.

- Parenteral oestrogen (polyoestradiol phosphate) to avoid first-pass hepatic metabolism was as effective as CAB for survival, but with still more non-fatal cardiovascular events [549].
- The use of either warfarin sodium, 1 mg/day, or aspirin, 75-100 mg/day in combination with DES, 1 mg/day or 3 mg/day, did not suppress the thromboembolic complications associated with DES [550, 551].

These results precluded oestrogen as a standard first-line treatment.

6.5.4 *Luteinising-hormone-releasing hormone agonists*

Long-acting LHRH agonists are currently the main forms of ADT. These synthetic analogues of LHRH, are delivered as depot injections on a 1-, 2-, 3-, 6-monthly, or yearly basis. After the first injection, they stimulate pituitary LHRH receptors, inducing a transient rise in LH and FSH leading to the 'testosterone surge' or 'flare-up' phenomenon, which begins 2-3 days later and lasts for about 1 week. The different products have practical differences that need to be considered in everyday practice, including the storage temperature, whether a drug is ready for immediate use or requires reconstitution, and whether a drug is given by subcutaneous or intramuscular injection.

6.5.4.1 *Achievement of castration levels*

Chronic exposure to LHRH agonists results in the down-regulation of LHRH-receptors, suppressing LH and FSH secretion and therefore testosterone production. The castration level is usually obtained within 2-4 weeks [552]. However, about 10% of treated patients fail to achieve castration levels [543], which rise to 15% if the castration threshold is defined as 1 nmol/l. Although there is no formal direct comparison between the various compounds, they are considered to be equally active [548] and comparable to orchiectomy [549].

6.5.4.2 *Flare-up phenomenon*

The 'flare phenomenon' might lead to detrimental effects such as increased bone pain, acute bladder outlet obstruction, obstructive renal failure, spinal cord compression, and cardiovascular death due to hypercoagulation status.

Clinical flare needs to be distinguished from the biochemical flare and even from asymptomatic radiographic evidence of progression [553]. Patients at risk are usually those with high-volume, symptomatic, bony disease. Concomitant therapy with an anti-androgen decreases the incidence of clinical flare, but does not completely suppress the risk.

Some testosterone mini-flares have also been observed with the LHRH agonists. The clinical impact might be associated with a negative impact on OS (see Section 6.6.3.1).

6.5.5 *Luteinising-hormone-releasing hormone antagonists*

LHRH antagonists bind immediately and competitively to LHRH receptors in the pituitary gland. The effect is a rapid decrease in LH, FSH and testosterone levels without any flare. The practical shortcoming of these compounds is the lack of a long-acting depot formulation.

6.5.5.1 *Abarelix*

Abarelix was as effective as LHRH agonists in achieving and maintaining castration levels of testosterone and in reducing serum PSA [554, 555]. However, the FDA has issued a warning about allergic reactions with the

long-term use of abarelix, which has resulted in suspension of its further development. It is, however, licensed in metastatic and symptomatic PCa, for which no other treatment option is available, or as a short-term induction modality (http://www.accessdata.fda.gov/drugsatfda_docs/label/2003/21320_plenaxis_lbl.pdf).

6.5.5.2 *Degarelix*

Degarelix is an LHRH antagonist with a monthly subcutaneous formulation. The standard dosage of degarelix is 240 mg in the first month, followed by 80 mg monthly injections. More than 95% of patients have achieved a castrate level at day 3. No allergic reactions were observed. Its main specific side-effect is a somewhat painful injection (moderate or mild) reported by 40% of patients, mainly after the first injection. An extended follow-up has been published, suggesting a better progression-free survival compared to monthly leuporelin [556]. Its definitive superiority over the LHRH analogues remains to be proven. Their use is limited by a monthly formulation.

6.5.6 **Anti-androgens**

These oral compounds are classified according to their chemical structure as:

- steroidal, e.g. cyproterone acetate (CPA), megestrol acetate and medroxyprogesterone acetate;
- non-steroidal or pure, e.g. nilutamide, flutamide and bicalutamide.

Both classes compete with androgens at the receptor level. This is the sole action of non-steroidal antiandrogens that leads to an unchanged or slightly elevated testosterone level. Conversely, steroidal antiandrogens have progestational properties leading to a central inhibition by crossing the blood-brain barrier.

6.5.6.1 *Steroidal anti-androgens*

These compounds are synthetic derivatives of hydroxyprogesterone. Their main pharmacological side-effects are secondary to castration, while gynaecomastia is quite rare. The non-pharmacological side effects are cardiovascular toxicity (4-40% for CPA) and hepatotoxicity.

6.5.6.1.1 *Cyproterone acetate (CPA)*

This was the first anti-androgen to be licensed, but the least studied. Its most effective dose in monotherapy is still unknown. Although CPA has a relatively long half-life (31-41 hours), it is usually administered in two or three fractionated doses of 100 mg each. Only one randomised trial [557] compared CPA with standard medical castration, suggesting a poorer OS compared to LHRH analogues. Although there are other studies in CPA monotherapy, methodological limitations prevent firm conclusions.

An underpowered monotherapy comparison with flutamide in M1b PCa did not show any difference in specific- and overall survival at a median follow-up of 8.6 years [558].

6.5.6.1.2 *Megestrol acetate and medroxyprogesterone acetate*

Very limited information is available on these two compounds, but they are associated with a poor overall efficacy [559].

6.5.6.2 *Non-steroidal anti-androgens*

Non-steroidal anti-androgens monotherapy have been promoted on the basis of improved quality of life (QoL) and compliance compared to castration. They do not suppress testosterone secretion and it is claimed that libido, overall physical performance and bone mineral density (BMD) are preserved [560]. Non-androgen pharmacological side-effects differ, with bicalutamide showing a more favourable safety and tolerability profile than nilutamide and flutamide [561]. All three agents share a common liver toxicity (occasionally fatal) and liver enzymes must be monitored regularly.

6.5.6.2.1 *Nilutamide*

There are no comparative trials of nilutamide monotherapy with castration. Non-androgen pharmacological side-effects are visual disturbances (i.e. delayed adaptation to darkness), alcohol intolerance, nausea, and specifically exceptional interstitial pneumonitis (potentially life-threatening). Nilutamide is not licensed for monotherapy.

6.5.6.2.2 *Flutamide*

Flutamide has been studied as monotherapy for more than 20 years. No dose-finding studies against a currently accepted endpoint (e.g. PSA response) are available. Flutamide is a pro-drug, and the half-life of the active metabolite is 5-6 hours, so it must be administered three times daily. The recommended daily dosage is 750 mg. The non-androgen pharmacological side-effect of flutamide is diarrhoea.

6.5.6.2.3 Bicalutamide

The dosage licensed for use in CAB is 50 mg/day, and 150 mg for monotherapy. The androgen pharmacological side-effects are mainly gynaecomastia (70%) and breast pain (68%), which may be prevented by anti-oestrogens [562, 563], prophylactic radiotherapy [559], or surgical mastectomy. However, bicalutamide monotherapy clearly offers bone protection compared with LHRH analogues and probably LHRH antagonists [560, 564].

6.5.7 **New compounds (for the castrate resistant status only)**

During castration, the occurrence of castration-resistant status (CRPC) is systematic. It is thought that it is mediated through two main overlapping mechanisms, which are androgen-receptor (AR)-independent and AR-dependent (see Section 6.11 - Castrate-resistant Prostate Cancer). In CRPC, the intracellular androgen level is increased compared to androgen sensitive cells, and an over-expression of the AR has been observed in CRPC, suggesting an adaptative mechanism [565]. This has led to the development of two new major compounds targeting the androgen axis: abiraterone acetate and enzalutamide.

6.5.7.1 *Abiraterone acetate*

Abiraterone acetate (AA) is a CYP17 inhibitor (a combination of 17 hydrolase and a 17-20 lyase inhibition). It represents an improvement over ketoconazole, which is no longer available. By blocking CYP 17, AA significantly decreases the intracellular testosterone level by suppressing its synthesis at the adrenal level inside the cancer cells (intracrine mechanism). This compound must be used together with prednisone/prednisolone (2 x 5 mg).

6.5.7.2 *Enzalutamide*

Enzalutamide (previously known as MDV 3100) is a novel anti-androgen with a higher affinity than bicalutamide for the AR receptor. While non-steroidal anti-androgens still allow transfer of ARs to the nucleus, enzalutamide also blocks AR transfer and therefore suppresses any possible agonist-like activity.

Both drugs were developed for use in mCRPC after docetaxel. Both drugs have resulted in a significant overall improvement in survival [566, 567]. Detailed results are presented in section 6.11 - Castrate-resistant Prostate Cancer).

6.5.8 **Cost-effectiveness of hormonal therapy options**

A formal meta-analysis and literature review evaluated the cost-effectiveness of various long-term androgen suppression options in advanced PCa (e.g. bilateral orchiectomy, DES, LHRH-agonist, NSAA monotherapy, and CAB using NSAA). For men who can accept it, bilateral orchiectomy is the most cost-effective form of ADT, providing a higher quality-adjusted survival, while CAB is the least economically attractive option, yielding small health benefits for a high relative cost. Furthermore, the greatest QoL gains and least costs may be obtained by starting ADT when symptoms from distant metastases have occurred [568]. Finally, once ADT is started, if a major response is obtained, IAD might be a useful way to lower treatment costs.

6.6 **Treatment: Metastatic prostate cancer**

6.6.1 **Introduction**

A systematic review of ADT in PCa has recently been published [541].

6.6.2 **Prognostic factors**

In recent years, the median survival of patients with newly diagnosed metastases is 42 months [569]. The M1 population is heterogeneous, with the most convincing data on prognosis produced by the large SWOG 8894 trial [570] discriminating patients into three groups based on the location of metastases (axial bone only compared to appendicular or visceral), the performance status (< 1 compared to ≥ 1), the Gleason score (< 8 compared to ≥ 8) and the PSA (< 65 compared to > 65 ng/mL). Patients with axial bone metastases only or appendicular or visceral metastases, an PS < 1 and a Gleason score < 8 have a median survival of 54 months, compared to those with appendicular or visceral metastases a PS ≥ 1 and a PSA > 65 with only 21 months median survival.

After starting ADT, the PSA level after 7 months of ADT may lead to 3 groups with very different survival expectancy. The median survival is 75 months if the PSA level < 0.2 ng/mL, 44 months if the PSA < 4 ng/mL and only 13 months if the PSA is > 4 ng/mL [571]. Although these predictions are based on data from the large SWOG 9346 cohort, the prognostic use of PSA at 7 months of ADT still requires independent confirmation.

6.6.3 **First-line hormonal treatment**

Primary ADT is the standard of care [541]. There is no level 1 evidence to choose between an LHRH analogue

or antagonist, except in patients with an impending spinal cord compression. In these patients, the choice for first-line treatment is between bilateral orchidectomy and an LHRH antagonist.

6.6.3.1 *Prevention of flare-up*

Starting with an LHRH analogue results in an initial testosterone flare, which can usually be prevented by starting an anti-androgen at the same time [572]. Prevention of flare-up is important in symptomatic patients or when a clinical flare might lead to severe complications. The anti-androgen is usually continued for 4 weeks, although this duration is not based on evidence since there are no trials of the best regimen for preventing flare-up. In addition, the long-term impact of preventing flare-up is unknown [573].

6.6.4 **Combination therapies**

6.6.4.1 *Complete androgen blockade (CAB)*

There are conflicting results from the many studies comparing CAB with monotherapy [572]. The largest RCT in 1,286 M1b patients found no difference between surgical castration plus flutamide compared to surgical castration without flutamide [574]. Systematic reviews have shown that CAB using non-steroidal anti-androgen (NSAA) appears to provide a small survival advantage (< 5%) vs. monotherapy (surgical castration or LHRH agonists) [575, 576] beyond 5 years [577]. However, some of the larger trials included in these reviews were methodologically flawed and it is unlikely that this small advantage, if any, is useful in daily clinical practice. LHRH analogues and NSAA have the highest estimated quality-adjusted survival. However, the use of CAB increases side effects and the economic cost. There is an incremental cost of more than US\$1 million per quality-adjusted life-year vs. orchiectomy alone.

6.6.4.2 *Non-steroidal anti-androgen (NSAA) monotherapy*

A systematic review has been published comparing non-steroidal antiandrogen monotherapy to castration (either medical or surgical) by the Cochrane group [578]. The key message is that use of non-steroidal antiandrogen monotherapy compared with medical or surgical castration monotherapy for advanced PCa is less effective in terms of OS, clinical progression, treatment failure and treatment discontinuation due to adverse events. The evidence quality was rated as moderate.

6.6.4.3 *Intermittent versus continuous androgen deprivation therapy (IAD)*

Long-term castration stimulates prostate cell apoptosis. After an average period of 24 months, the tumour relapses, characterised by a castrate-independent state of growth. Experimental data indicate that castrate-independent progression may begin early after castration, coinciding with the cessation of androgen-induced differentiation of stem cells [579]. It has been suggested that stopping castration prior to progression would mean that any subsequent tumour growth would be solely sustained by the proliferation of androgen-dependent stem cells. The stem cells should therefore be susceptible once again to androgen withdrawal. Thus, IAD could delay the emergence of the androgen-independent clone. This rationale has been developed mainly through models (e.g. the Shionoggi breast model), which may be significantly different to tumour behaviour in men. Other possible benefits of IAD include the preservation of QoL in off-treatment periods and a reduction in treatment cost.

IAD is feasible and accepted by patients [580]. Two independent reviews [581, 582] summarised the clinical efficacy of this attitude. They were based on seven RCTs. Of the seven trials, only three trials were in patients with M1 disease. The three remaining trials were combinations of different relapse situations, mainly locally advanced and metastatic cases.

The design of the seven trials is summarised in Table 6.6.1, while the main results for survival are summarised in Table 6.6.2. The most important survival finding was the lack of a significant difference in OS between continuous and intermittent ADT. Table 6.6.3 summarises the expected treatment benefits of IAD. The most important finding was that the benefit in overall QoL was at best minimal if any. However, some treatment side effects were decreased using IAD.

Table 6.6.1: Patient population and treatment cycles in phase III trials on IAD in M1 patients

Parameter	SEUG9401 [583]	FINN VII [584]	SWOG9346 [585]	TULP [586]	TAP22 [587]	De Leval [588]

Long-term consequences	Cardiovascular deaths: IAD 13.1% Continuous 16.7%	Cardiovascular deaths: IAD 12.8% Continuous 15.4%	-	-	-
QoL	Overall no clinically relevant differences. Favourable for IAD in sexual function domains	Favourable for IAD in activity limitation, physical capacity and sexual functioning domains	-	No clinically relevant difference	No clinically relevant difference

IAD = intermittent androgen deprivation; QoL = quality of life.

- The SWOG 9346 [585] is the largest-ever conducted trial in M1b patients. Out of 3,040 selected patients, only 1,535 were randomised based on the inclusion criteria. This highlights again that at best only 50% of M1b patients might be candidates for IAD, i.e. the best PSA responders.
- The SWOG 9346 was a non-inferiority trial. The results are inconclusive: (HR: 1.1; CI: 0.99-1.23), with the upper limit being above the pre-specified 90% upper limit of 1.2.

6.6.4.3.1 Potential other benefits of intermittent androgen deprivation

Other possible long-term benefits include bone protection [589] and/or a protective effect against the metabolic syndrome. Testosterone recovery is seen in most studies [580], leading to an intermittent castration. Finally, IAD is associated with a very significant decrease in the treatment cost.

6.6.4.3.2 Practical aspects for intermittent androgen deprivation

The optimal thresholds at which ADT must be stopped or resumed are empirical [580, 582]. Nevertheless, several points are clear.

- IAD is based on intermittent castration. Therefore, only drugs leading to castration are suitable for use in IAD.
- Most published experiences are based on CAB, which is considered as standard treatment. An LHRH antagonist might be a valid alternative [2], without any significant benefits.
- The induction cycle must last 9 months at the most, otherwise testosterone recovery is unlikely.
- The treatment is stopped only if patients have fulfilled all the following criteria:
 - well-informed and compliant patient;
 - no clinical progression;
 - clear PSA response, empirically defined as a PSA < 4 ng/mL in metastatic disease.
- Strict follow-up is mandatory, with clinical examination every 3-6 months. The more advanced the disease, the closer the follow-up. The same laboratory should be used to measure the PSA level.
- Treatment is resumed when the patient reaches either a clinical progression, or a PSA above a predetermined, empirically fixed, threshold: usually 10-20 ng/mL in metastatic cases.
- The same treatment is used for at least 3-6 months.
- Subsequent cycles of treatment are based on the same rules until the first sign is seen of a castrate-resistant status.
- The best population for IAD has still to be fully characterised. However, the most important factor seems to be the patient's response to the first cycle of IAD, e.g. the PSA level response [582].

IAD might be an option in metastatic situations after a standardised induction period, even if the benefits are fewer compared to those with less advanced situations.

6.6.4.4 *Immediate versus deferred androgen deprivation therapy*

There is no discussion regarding the introduction of IAD in symptomatic patients. However, there is still controversy concerning the best time to introduce hormonal therapy in asymptomatic metastatic patients due to the lack of properly conducted RCTs. These are underpowered trials with heterogeneous patient enrolment (i.e. locally advanced, M1a, M1b status) and variations in ADT modalities and follow-up schedules.

ADT was shown to be the most cost-effective therapy if started at the time the patient developed symptomatic metastases [568].

The Cochrane Library review extracted four good-quality RCTs: VACURG I and II trials, the MRC trial, and the ECOG 7887 study. These studies were all conducted in the pre-PSA era and included patients with advanced PCa, who had received early vs. deferred ADT, either as primary therapy or adjuvant to radical prostatectomy [590]. The Cochrane review found that the M1a/b population showed no improvement in OS, although early ADT significantly reduced disease progression and complication rates due to progression.

Based on a systematic review of the literature, the ASCO guidelines on initial hormonal treatment for androgen-sensitive, metastatic, recurrent or progressive PCa concluded it was not possible to make a recommendation on when to start hormonal therapy in advanced asymptomatic PCa [591]. The ESMO guidelines do not make any statement [592].

6.6.5 *Hormonal treatment combined with chemotherapy*

Two large RCT were conducted, one is fully published [593], the second one just presented recently [594], but representing a cohort twice as large. They both compared ADT alone as standard with AT combined with upfront Docetaxel. They came to different findings regarding survival benefit and it is not possible to make a clear recommendation at the present time.

6.6.6 *Guidelines for the first-line treatment of metastatic prostate cancer*

	Modality	Recommendation	LE	GR
Castration alone	Surgical: agonist, antagonist.	Standard of care	1b	A
	New hormonal treatment (Abiraterone acetate, Enzalutamide)	To be used in an experimental setting only.	4	A
Castration combined with chemotherapy	Docetaxel combined with castration.	No specific recommendation can be made.	1b	A
Castration combined with any other local treatment	Radiotherapy or surgery	To be used in an experimental setting only.	3	A

6.6.7 *Guidelines for hormonal treatment of metastatic prostate cancer*

Recommendations	LE	GR
In M1 symptomatic patients, immediate castration should be offered to palliate symptoms and reduce the risk for potentially catastrophic sequelae of advanced disease (spinal cord compression, pathological fractures, ureteral obstruction, extraskelatal metastasis).	1b	A
In M1 asymptomatic patients, immediate castration should be offered to defer progression to a symptomatic stage and prevent serious disease progression-related complications.	1b	A
In M1 asymptomatic patients, deferred castration should be discussed with a well-informed patient.	2b	B
Anti-androgens		
In M1 patients, short-term administration of anti-androgens is recommended to reduce the risk of the 'flare-up' phenomenon in patients with advanced metastatic disease who are to receive an LHRH agonist.	2a	A
In M1 patients, short-term administration of anti-androgens should be given for some weeks only (starting treatment on the same day as an LHRH analogue is started or for up to 7 days before the first LHRH analogue injection).	3 4	A B
In M1 patients, administration of anti-androgens as monotherapy should not be considered.	1a	A

Intermittent treatment			
Population	In asymptomatic M1 patients, intermittent treatment can be offered to highly motivated men, with a major PSA response after the induction period.	1b	B
Threshold to start and stop ADT	In M1 patients, timing of intermittent treatment should follow the schedules currently in use in clinical trials. Treatment is usually stopped when the PSA level is < 4 ng/mL after 6 to 7 months of treatment. Treatment is resumed when the PSA is > 10-20 ng/mL.	4	C
Drug	Combined treatment with LHRH agonists and NSAA is recommended.	1b	A
	Antagonists might be an option.	4	B

ADT = androgen deprivation therapy; GR = grade of recommendation; LE = level of evidence; LHRH = luteinising hormone-releasing hormone; NSAA = non-steroidal anti-androgen; PSA = prostate specific antigen; RCT = randomised controlled trial.

6.6.8 Contraindications for various therapies

Therapy	Contraindications	LE	GR
Bilateral orchiectomy	Psychological reluctance to undergo surgical castration.	3	A
Oestrogens	Known cardiovascular disease.	2b	B
LHRH agonists monotherapy	Patients with metastatic disease at high risk for clinical 'flare-up' phenomenon.	2b	A

ADT = androgen deprivation therapy; GR = grade of recommendation; LE = level of evidence; LHRH = luteinising hormone-releasing hormone.

6.7 Management of prostate cancer in older men

6.7.1 Evaluating health status in senior adults

6.7.1.1 Introduction

With a median age at diagnosis of 68 years, PCa is generally a disease of men aged > 70 years. In the USA, the increase in men aged > 65 years will result in an estimated 70% increase in annual diagnosis of PCa by 2030 [595]. A similar increase is expected in Europe [4].

The Surveillance, Epidemiology and End Results (SEER) database shows that 71% of PCa-related deaths occur in men aged ≥ 75 years [596], probably due to the higher incidence of advanced/metastatic disease [597-599].

Despite the high incidence and mortality rates in senior adults, they may be undertreated in the USA [600] and Europe [601]. In the USA, only 41% of patients aged > 75 years with intermediate- and high-risk disease receive curative treatment compared to 88% aged 65-74 [602]. Two large studies showed that PCa-specific mortality was low for localised low- and intermediate-risk PCa, irrespective of age [329, 603]. In contrast, cancer-related mortality of up to 64% was found for high-risk PCa.

6.7.1.2 Evaluation of life expectancy, comorbidity and health status

In localised disease, > 10 years life expectancy is considered mandatory for any benefit from local treatment. Life expectancy varies within each age group. This can be explained by comorbidity, which is more important than age in predicting death in localised PCa [304]. Besides comorbidities, dependence in daily activities, malnutrition and cognitive impairment are associated with worse survival.

6.7.1.2.1 Comorbidity

Comorbidity is a major predictor of non-cancer-specific death in localised PCa treated with RP [604]. This was confirmed in a patient group who did not receive any form of local treatment within 180 days after diagnosis [304]. At 10 years, most men with a Charlson Comorbidity Index (CCI) score > 2 had died from competing causes, irrespective of age or tumour aggressiveness.

Currently, the Cumulative Illness Score Rating-Geriatrics (CISR-G; Table 6.7.1) [605] is the best tool for assessing mortality risk unrelated to PCa [606]. Although CCI measures only potentially lethal comorbidity, the CISR-G also rates non-lethal conditions [607].

Table 6.7.1: Cumulative Illness Score Rating-Geriatrics (CISR-G)

Cumulative Illness Rating Scale			
Patient		Age	
Rater		Date	
Rating strategy			
0		None	
1		Mild (or past significant problem)	
2		Moderate (moderate disability or morbidity, requires first-line therapy)	
3		Severe (constant significant disability/ uncontrollable chronic problems)	
4		Extremely severe (immediate treatment required/ end organ failure / severe impairment in function)	
		Score

Endocrine/metabolic			
Psychiatric illness			
Total score			

Patients are considered fit if they have no Grade 3 score

Vulnerable: one or two Grade 3 scores

Frail: > 2 Grade 3, or any Grade 4 scores

Too sick: multiple Grade 4 scores

6.7.1.2.2 Independent daily activities

The level of dependence in daily activities influences survival in senior adults [608-610]. The Activities of Daily Living (ADL) scale rates accomplishment of basic activities of daily living, while the Instrumental Activities of Daily Living (IADL) scale rates activities requiring higher cognition and judgement.

6.7.1.2.3 Malnutrition

Malnutrition is associated with increased mortality in senior patients [611]. Nutritional status can be estimated from body weight during the previous 3 months:

- Good nutritional status < 5% weight loss;
- Risk of malnutrition: 5-10% weight loss;
- Severe malnutrition: > 10% weight loss.

6.7.1.2.4 Cognitive impairment

Cognitive impairment is associated with increased mortality risk in senior adults [612]. In patients undergoing major elective surgery, there is an association between baseline cognitive impairment and long-term postoperative complications and mortality [613]. Intervention is unlikely to reverse cognitive impairment, except in depression [40].

6.7.1.2.5 Baseline screening using the G8 screening tool

The International Society of Geriatric Oncology (SIOG) Prostate Cancer Working Group (PCWG) recommends that treatment for senior adults should be based on systematic evaluation of health status [40]. The G8 (Geriatric 8) health status screening tool is described in Table 6.7.2, the Karnofsky and ECOG Scores in Table 6.7.3 [614].

Table 6.7.2: G8 screening tool (Adapted from [615])

	Items	Possible responses (score)
A	Has food intake declined over the past 3 months due to loss of appetite, digestive problems, chewing, or swallowing difficulties?	0 = severe decrease in food intake
		1 = moderate decrease in food intake
		2 = no decrease in food intake
B	Weight loss during the last 3 months?	0 = weight loss > 3 kg
		1 = does not know
		2 = weight loss between 1 and 3 kg
		3 = no weight loss
C	Mobility?	0 = bed or chair bound
		1 = able to get out of bed/chair but does not go out
		2 = goes out
E	Neuropsychological problems?	0 = severe dementia or depression
		1 = mild dementia
		2 = no psychological problems
F	BMI? (weight in kg)/(height in m ²)	0 = BMI < 19
		1 = BMI 19 to < 21
		2 = BMI 21 to < 23
		3 = BMI ≥ 23
H	Takes more than three prescription drugs per day?	0 = yes
		1 = no
P	In comparison with other people of the same age, how does the patient consider his/her health status?	0.0 = not as good
		0.5 = does not know
		1.0 = as good
		2.0 = better
	Age	0: > 85
		1: 80-85
		2: < 80
	Total score	0-17

G8 score > 14 shows that patients should receive the same treatment as younger patients. Patients with $G8 \leq 14$ should undergo full geriatric evaluation, assessing comorbidity, nutritional status, and cognitive and physical functions, to determine if the impairment is reversible [615]. Patients with reversible impairment (vulnerable patients) should be treated according to EAU Guidelines. Patients with irreversible impairment (frail patients) should receive adapted treatment [40].

Table 6.7.3: Performance Scales - Karnofsky & ECOG Scores [614]

Karnofsky Status	Karnofsky Grade	ECOG Grade	ECOG Status
Normal, no complaints.	100	0	Fully active, able to carry on all pre-disease performance without restriction.
Able to carry on normal activities. Minor signs or symptoms of disease.	90	1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work.
Normal activity with effort.	80	1	Restricted in physically strenuous activity but ambulatory and able to carry out work of a light or sedentary nature, e.g., light house work, office work.
Care for self. Unable to carry on normal activity or to do active work.	70	2	Ambulatory and capable of all selfcare but unable to carry out any work activities. Up and about more than 50% of waking hours.
Requires occasional assistance, but able to care for most of his needs.	60	2	Ambulatory and capable of all selfcare but unable to carry out any work activities. Up and about more than 50% of waking hours.
Requires considerable assistance and frequent medical care.	50	3	Capable of only limited selfcare, confined to bed or chair more than 50% of waking hours.
Disabled. Requires special care and assistance.	40	3	Capable of only limited selfcare, confined to bed or chair more than 50% of waking hours.
Severely disabled. Hospitalisation indicated though death nonimminent.	30	4	Completely disabled. Cannot carry on any selfcare. Totally confined to bed or chair.
Very sick. Hospitalisation necessary. Active supportive treatment necessary.	20	4	Completely disabled. Cannot carry on any selfcare. Totally confined to bed or chair.
Moribund	10	4	Completely disabled. Cannot carry on any selfcare. Totally confined to bed or chair.

6.7.1.2.6 Conclusions

Systematic assessment, using the G8 tool, is recommended by The SIOG PCWG [40]. Patients with G8 score < 14 should undergo complete geriatric assessment to evaluate reversibility of any impairments [40].

Senior adults can be classified into one of four groups regarding health status based on G8 score > 14 (patient considered fit), or score < 14 (patient considered vulnerable or frail). The treatment policy is then:

- fit or healthy older men should receive standard treatment;
- vulnerable patients may receive standard treatment after resolution of any geriatric problems;
- frail patients should receive adapted treatment;
- patients who are too sick with terminal illness should receive only palliative treatment [40].

After resolution of reversible impairments, a similar urological approach should be carried out in fit or vulnerable patients [1, 2]. Older men with PCa should be managed according to their individual health status, which is directed by the presence of any associated comorbidity and not age.

6.7.1.3 Guidelines for the evaluation of health status in elderly men

	LE	GR
Senior adults with localised PCa should systematically undergo health status screening	1b	A
Health status screening should be performed using the G8 screening tool	2a	A
Patients with G8 score ≤ 14 should undergo full specialist geriatric evaluation	2a	A
Senior adults can be classified as follows:	3	B
1. Fit or healthy older men, should receive standard treatment;		
2. Vulnerable patients (reversible impairment) may be given standard treatment after resolution of geriatric problems;		
3. Frail patients (irreversible impairment) should receive adapted treatment;		
4. Patients who are too sick with terminal illness should receive only symptomatic palliative treatment.		

6.7.2 Specific aspects of PCa treatment in older men

6.7.2.1 Localised PCa

6.7.2.1.1 Deferred treatment (active surveillance, watchful waiting)

This has been described in Chapter 8 and 9. Active treatment mostly benefits patients with intermediate- or high-risk disease and longest expected survival. A recent study assessed the effect of age, health status and patient preferences on outcomes of surgery vs active surveillance for low risk PCa. As expected, older age and worse baseline health status were associated with a smaller benefit in prostate-cancer-specific mortality and life expectancy with surgery, and increased incremental years with treatment side effects. Older men and men in poor health were likely to have better quality adjusted life expectancy with active surveillance [327].

6.7.2.1.2 Radical prostatectomy

Senior adults (aged ≥ 75 years) are more likely to present with very advanced disease and have a greater risk of death from PCa, despite higher death rates from competing causes [597]. In the most recent update of the SPCG-4 study, randomising patients with localised PCa to RP vs watchful waiting, the benefit of surgery with respect to death from PCa was largest in the men younger than 65 years of age (relative risk, 0.45). However, radical prostatectomy was associated with a reduced risk of metastases and use of androgen deprivation therapy among older men (relative risk, 0.68 and 0.60, respectively) [311]. Risk of short-term complications after RP is related more to comorbidity severity than age. Conversely, risk of long-term incontinence is influenced more by increasing age [616, 617].

6.7.2.1.3 External beam radiotherapy

External beam radiotherapy (EBRT) and RP have similar cancer control and treatment-related comorbidity, regardless of age, assuming a dose of > 72 Gy when using intensity-modulated or image-guided radiotherapy [618].

The drawback of associating ADT with EBRT in senior adults is discussed in Chapter 12. Cardiac status should be assessed because ADT in patients with pre-existing heart conditions is associated with increased morbidity and mortality. Patients with moderate to severe comorbidities might not have a significant survival-benefit when associating ADT with EBRT [413].

6.7.2.1.4 Minimally invasive therapies

Minimally invasive energy-ablative therapies are being developed rapidly, but there is still a lack of evidence to support their use.

6.7.2.1.5 Androgen deprivation therapy

In patients with non-metastatic localised PCa not suitable for curative treatment, immediate ADT should be used only in patients requiring symptom palliation. In locally advanced T3-T4 disease, immediate ADT may benefit patients with PSA > 50 ng/mL and PSA-DT < 12 months [619, 620].

6.7.2.2 Advanced PCa

6.7.2.2.1 Hormone-naïve metastatic PCa

ADT is the first-line treatment in hormone-sensitive metastatic PCa. The SIOG PCWG recommends evaluation of baseline bone mineral density and prevention of osteoporosis by calcium and vitamin D supplements [40].

Routine bisphosphonates or denosumab to prevent skeletal complications in ADT is not recommended, unless

there is a risk of fracture, or castration-resistant PCa (CRPC) with skeletal metastasis [621].

6.7.2.2.2 Metastatic CRPC

In metastatic CRPC, docetaxel is standard in fit and vulnerable older men [622], with comparable response and tolerance to younger patients [623]. Tolerability has not been specifically studied in frail older men. In elderly and frail patients, granulocyte colony-stimulating factor prophylaxis should be considered.

Cabazitaxel, abiraterone acetate, enzalutamide, and sipuleucel-T increase survival in chemotherapy-treated and chemotherapy-naïve senior adults [566, 567, 624-628].

Palliative treatment includes surgery, radiopharmaceuticals, EBRT, and medical treatment for pain and symptoms.

6.7.2.3 Guidelines for the treatment of prostate cancer in older men

Treatment	LE	GR
<i>Localised disease</i>		
Fit and vulnerable senior adults with life expectancy > 10 years and high-risk disease should be offered standard treatment.	2b	A
In frail or 'too-sick' patients, immediate ADT should only be used for symptom palliation.	1b	A
Minimally invasive energy-ablative therapies should not be routine in senior adults. These only have a role in selected fit and vulnerable senior adults with intermediate-risk disease.	3	B
<i>Advanced disease</i>		
Evaluation of bone mineral status and prevention of osteoporotic fracture are recommended in patients at high-risk of fractures.	2b	A
New chemotherapeutic and hormonal agents can be used in fit and vulnerable adults.	1b	B

ADT = androgen deprivation therapy; GR = grade of recommendation; LE = level of evidence.

6.8 Treatment: Post-treatment quality of life in patients with localised prostate cancer

6.8.1 Introduction

Increased life expectancy in PCa makes post-treatment QoL a key issue. Health-related QoL (HRQoL) refers to the impact of disease and treatment on well-being and physical, emotional and social functioning, including daily functioning [629]. HRQoL is rated by patients, and is important because physicians often underestimate the impact of disease and treatment on patients [630].

PCa-specific HRQoL refers to the disease-specific outcome of PCa, including urinary, bowel and sexual functioning. General HRQoL refers to well-being, vitality, fatigue, pain, general health status, global QoL, and life satisfaction [631].

HRQoL is measured using standardised questionnaires, which provide an objective assessment of general and disease-specific domains [632, 633].

Comparison of the most common contemporary therapies for localised PCa is necessary to inform patients about treatment options and address patient preferences for the various possible outcomes. There is still limited objective data about HRQoL in PCa treatment.

6.8.2 Active surveillance and watchful waiting

Although active surveillance (AS) and watchful waiting (WW) avoids treatment-related side effects, they carry an increased risk of psychological distress, which significantly affects HRQoL [634]. Risk factors for not doing well on AS include: patient perception that the physician is making most of the decisions, poor physical health, high anxiety, high PSA, lack of a partner, mental impairment, recent diagnosis of PCa, and lower number of core samples taken at diagnostic biopsy. These factors are significantly associated with low HRQoL [635, 636]. Anxiety and distress remained low during the first 9 months of AS [636].

In contrast to AS, men managed with WW in SPCG-4 were not followed closely to induce curative treatment if needed, which could explain the less favourable anxiety and depression scores compared to the PRIAS results [637].

A long-term comparison of WW and RP [637] found that depression, well-being and psychological status did not differ significantly among treatment groups over 8 years. However, men in the RP group reported more physical symptoms related to leakage, erection and libido.

Apart from psychological distress, untreated men may have a higher level of irritative/obstructive urinary symptoms compared to patients treated with RP or radiotherapy after 1-3 years [638].

6.8.3 **Radical prostatectomy**

RP has a significant negative effect on multiple QoL domains, including sexual and urinary function, and physical HRQoL [639-641]. In the Prostate Cancer Outcomes Study (PCOS), at 2 years 8.7% of men had a lack of urinary control and 41.9% reported sexual dysfunction [642]. Recovery from sexual dysfunction and urinary incontinence occurs over 2-3 years [617, 643], with the latter being at its worst by 2 months after surgery [639].

Although some advances have reduced these side effects, such as nerve-sparing RP or robot-assisted radical prostatectomy (RALP), their impact on HRQoL remains controversial. Preserving neurovascular bundles aims to reduce erectile dysfunction [639, 644] and improves urinary function [645]. RALP and open RP have comparable functional outcomes and similar HRQoL scores [646]. There is no reliable data to compare HRQoL following RALP and laparoscopic RP. General HRQoL domains such as pain and energy worsen immediately post-RP, but usually improve by 12 months [643, 647].

New methods for reporting outcomes after RP combine major outcomes, including continence, potency and cancer control [309] and perioperative complications and positive surgical margins [648]. Pentafecta rates reflect postoperative expectations and satisfaction more accurately and are used in counselling patients with clinically localised PCa. The use of trifecta and pentafecta outcomes in postoperative HRQoL assessment needs further validation.

6.8.4 **External-beam radiotherapy and low-dose rate brachytherapy**

EBRT and I-125 low-dose rate (LDR) brachytherapy may cause urinary, sexual- and bowel dysfunction. Both methods can result in irritative voiding symptoms, such as urgency, frequency, and urge incontinence, that negatively affect overall urinary function and HRQoL [639]. In the radiotherapy group, urinary incontinence was reported to be at its worst by 2 months after surgery, but the effects of EBRT on urinary symptoms had resolved at 12 months and improved over baseline at 24 months [639]. Patients in the LDR brachytherapy group reported significant detriments in urinary irritation or obstruction and incontinence. At 1-2 years after LDR brachytherapy, incontinence was reported by 4-6% of patients. Eighteen percent of the LDR brachytherapy group and 11% of the EBRT group reported distress from overall urinary symptoms at 1 year [639].

EBRT and LDR brachytherapy significantly affected the bowel and rectal HRQoL domains [639], which were almost as important as urinary problems [649, 650]. Symptom onset occurred during or early after treatment, and sometimes persisted into follow-up. Rectal urgency, frequency, pain, faecal incontinence, or haematochezia-caused distress related to bowel function was reported in 9% of patients at 1 year after EBRT or LDR brachytherapy [639]. At 2 years after dose-escalated EBRT, $\leq 11\%$ of patients had problems with bowel HRQoL. Bowel HRQoL was related to baseline function, $\leq 25\%$ volume of rectum treated with 70 Gy, and aspirin [651]. Bowel and rectal symptoms were less severe after LDR brachytherapy than EBRT [632].

Significant deterioration in HRQoL was reported at 6 years after I-125 LDR brachytherapy, including urinary and bowel symptoms, pain, physical functioning, and sexual activity [652]. HRQoL scores returned close to baseline at 1 year and remained stable up to 6 years after treatment. The only clinically relevant changes occurred in emotional functioning and sexual activity. Dietary intervention did not significantly affect gastrointestinal side effects or other aspects of HRQoL in patients undergoing RT [653].

Adjuvant androgen suppression may exacerbate the adverse effects of EBRT or LDR on sexuality, vitality [639] and long-term bowel function [654].

Fatigue is commonly reported following EBRT, with the highest level seen at the end of treatment. 4% of patients reported severe fatigue 5-years post-treatment, adversely affecting QoL [655]. Men treated with interstitial LDR brachytherapy had only slight declines in general HRQoL. Physical and functional status declines have been reported in the first few months after implantation, but pretreatment function was regained by most men after 1 year [652].

6.8.4.1 **Radiotherapy toxicity**

Patients must be informed about acute and late genitourinary or gastrointestinal toxicity and the impact of irradiation on erectile function. In contemporary practice, the NCIC toxicity grading system is increasingly used, but most studies have used the RTOG scales, which are described in Tables 6.8.1 and 6.8.2. Risk factors for acute or late gastrointestinal toxicities after RT include advanced age, preexisting diabetes mellitus, haemorrhoids, inflammatory bowel disease, a history of prior abdominal surgery, larger rectal volume and the concomitant use of androgen deprivation [466].

Pre-treatment genitourinary complaints, prior transurethral resection of the prostate and the presence of acute genitourinary toxicity are suggested as contributing to long-term urinary morbidity.

Table 6.8.1: Acute gastrointestinal and genitourinary complications according to the Radiation Therapy Oncology Group (RTOG)/European Organisation for Research and Treatment of Cancer morbidity scale (adaptations with regard to the original RTOG scale in italics) according to Huang et al. [656]*

	Grade 1	Grade 2	Grade 3	Grade 4
GI	Increased frequency or change in quality of bowel habits not requiring medication. Rectal discomfort not requiring analgesics.	Diarrhoea requiring parasympatholytic drugs. Mucous discharge not necessitating sanitary pads. Rectal or abdominal pain requiring analgesics.	Diarrhoea requiring parenteral support. Severe mucous or blood discharge necessitating sanitary pads. Abdominal distension (flat plate radiograph demonstrates distended bowel loops).	Obstruction, fistula, or perforation GI bleeding requiring transfusion; Abdominal pain or tenesmus requiring tube decompression or bowel diversion.
GU	Frequency of urination or nocturia twice pretreatment habit. Dysuria or urgency not requiring medication.	Frequency of urination is less frequent than every hour (<i>day: 12-16 times; nocturia 5-8 times</i>). Dysuria, urgency, bladder spasm requiring local anaesthetic.	Frequency of urination is more frequent than every hour (<i>day: > 16 times; nocturia: > 8 times</i>). Dysuria, bladder spasm, urgency requiring frequent regular narcotic. Gross haematuria <i>complaints requiring permanent or suprapubic catheter.</i>	Haematuria requiring transfusion. Obstruction not resulting from clots. Ulceration Necrosis

*Reproduced with permission of Elsevier, from Budäus L et al. Eur Urol 2012 Jan;61(2):112-7.

GI = gastrointestinal; GU = genitourinary.

Table 6.8.2: Late gastrointestinal and genitourinary complications according to the Radiation Therapy Oncology Group (RTOG)/European Organisation for Research and Treatment of Cancer (EORTC) morbidity scale (adaptations with regard to the original RTOG/EORTC scale in *italics*) according to Huang et al. [656]*

	Grade 1	Grade 2	Grade 3	Grade 4
GI*	Mild diarrhoea Mild cramping Bowel movements 2-5 per day Slight rectal discharge or bleeding	Moderate diarrhoea Intermittent, severe cramping. Bowel movements (5 per day). <i>Moderate excessive, rectal discharge. Intermittent, frequent bleeding (3 single laser treatments or transfusion).</i>	<i>Watery diarrhoea</i> Obstruction requiring surgery. Bleeding requiring surgery or 2 <i>laser treatments or transfusions.</i>	Necrosis Perforation Fistula <i>Abdominal pain or tenesmus requiring tube decompression or bowel diversion.</i>
GU	<i>Frequency during day 0.5-1 h</i> <i>Nocturia 2-3/night</i> <i>Slight dysuria or microscopic haematuria requiring no medication</i> <i>Slight epithelial atrophy, minor telangiectasia</i> <i>Bladder capacity > 300 mL</i>	<i>Frequency during day: 1-2 h</i> <i>Nocturia 4-6/night</i> <i>Moderate dysuria or intermittent (mild, moderate) haematuria requiring medication†</i> <i>Moderate telangiectasia</i> <i>Bladder capacity: 150-300 mL</i>	<i>Frequency during day: 2 h</i> <i>Nocturia 6/night</i> Severe dysuria Frequent (severe) haematuria Severe telangiectasia Bladder capacity: 100-150 mL <i>Benign urethral strictures requiring TURP, dilation, or suprapubic or permanent catheter</i>	Necrosis Severe haemorrhagic cystitis Bladder capacity > 100 mL

* The difference between grade 1 and grade 2 GI pain, mucosal loss, or bleeding is most easily made when grade 2 is defined as morbidity requiring specific medication: grade 1 = stool softener, diet modification, occasional (< 2/wk) non-narcotic drug, occasional antidiarrhoeal agent (2/wk), occasional use of incontinence pads (1-2 d/wk); grade 2 = regular (> 2/wk) use of (non)narcotic drugs for pain, regular (2/wk) antidiarrhoeals, steroid suppositories, one laser.

† With the exception of antibiotics.

GI = gastrointestinal; GU = genitourinary; TURP = transurethral resection of the prostate.

6.8.5 Complications of high-intensity focused ultrasound

Urinary retention appears to be one of the most common side-effects of HIFU, developing in almost all patients, with the mean interval of catheterization via a suprapubic tube varying between 12 and 35 days [511, 514, 515]. Grade I and II urinary stress incontinence occurs in about 12% of patients. Subsequent TURP or bladder neck incision to treat subvesical obstruction is common, and is sometimes even performed at the time of HIFU. Post-operative impotence occurs in 55-70% of patients.

Elterman et al. [657] have treated 95 patients with clinically organ-confined PCa using the Sonablate 500 device (SonaCare Medical, Charlotte, NC, USA) and have evaluated the type and frequency of treatment-associated complications. With a minimum follow-up of six months, 17% (7/41) of the men had significant incontinence, and 2% developed significant erectile dysfunction. Early and late subvesical obstruction necessitating surgical treatment occurred in 17 (17.9%) and 20 (21.1%) patients, respectively.

Moderate to severe stress urinary incontinence was rare, occurring in fewer than 6.4% of men, and decreased in more recent treatment to 3.1% [517]. Acute urinary retention was seen in 7.6% of men. Even in more recent treatment, the rate of urethral-rectal fistula was 0.7%.

6.8.6 Cryotherapy

Quality of life and sexuality following CSAP were investigated in a clinical phase II trial that recruited 75 men [658]. Quality-of-life analysis by the prostate-specific FACT-P questionnaire showed that most subscales return to pre-treatment levels by 12 months after CSAP. Furthermore, no significant changes were seen when

comparing data at 36 months with those at 12 months. With regard to sexuality, 37% of men were able to have intercourse three years after CSAP.

In a prospective, randomised clinical trial, 244 men with newly diagnosed organ-confined PCa were randomised to receive either external-beam radiation therapy (EBRT) or to undergo CSAP [659]. After a follow-up of three years, sexual function was significantly less impaired in the EBRT group.

6.8.7 Hormonal therapy

There is a lack of data on the effects of hormonal treatment on QoL, with only a single, large, prospective, RCT comparing orchiectomy + flutamide or placebo in M1 patients. Combined therapy resulted in a lower QoL in the first 6 months, with more frequent diarrhoea and worse emotional functioning, compared with castration alone [660]. A small RCT evaluated the health-related quality of life (HRQoL) at 1-year follow-up in patients with non-localised PCa, between various ADT, or no treatment. Both sexual and cognitive function significantly declined with ADT, while emotional distress significantly increased if no treatment [661]. A prospective observational study of non-metastatic PCa, found that immediate ADT was associated with a lower overall QoL compared to deferred treatment [662]. Another retrospective, non-randomised study suggested that men receiving LHRH agonists reported more worry and physical discomfort and poorer overall health, and were less likely to believe themselves free of cancer than did orchiectomised patients. The stage at diagnosis had no effect on health outcome [663].

Using a specific non-validated questionnaire, bicalutamide monotherapy showed a significant advantage over castration in the domains of physical capacity and sexual interest (not sexual function) at 12 months [664]. A post-hoc analysis, including only patients with sexual interest suggested that bicalutamide was associated with better sexual preservation, including maintained sexual interest, feeling sexually attractive [665], preserved libido and erectile function [666].

Intermittent androgen deprivation has been discussed elsewhere (see Section 6.6 - Metastatic Prostate Cancer - Hormonal therapy).

6.8.7.1 Side-effects, quality of life and cost of hormonal therapy

The many deleterious side-effects of long-term ADT have been well known for years. As the use of ADT increases, it is increasingly important to consider these side-effects. A systematic review of the side-effects of long-term ADT has been recently published [667].

6.8.7.1.1 Sexual function

Loss of libido and erectile dysfunction are usual. The management of acquired erectile dysfunction is mostly non-specific [668].

6.8.7.1.2 Hot flushes

They are the most common side-effect of ADT. They appear 3 months after starting ADT, usually persist long-term and have may a significant impact on QoL.

Oestrogen-receptor modulators or low-dose oestrogen therapies, e.g. DES, 0.5-1 mg/day, reduce the frequency and severity of hot flushes. Both treatments carry a risk of cardiovascular complications. Soya phytoestrogens have shown an efficacy in breast cancer patients, but have not been evaluated in men. Progesterone-based treatments have demonstrated efficacy with 80% of patients showing an improvement [669].

Serotonin reuptake inhibitors (e.g. venlafaxine or sertraline) appear to be effective in men, but less than hormonal treatments based on a prospective randomised trial comparing venlafaxine, 75 mg daily, with medroxyprogesterone, 20 mg daily, or CPA, 100 mg daily [670]. After 6 months of LHRH (n = 919), 311 men had significant hot flushes and were randomised to one of the treatments. Venlafaxine was clearly inferior compared to the hormonal agents, which showed similar efficacy to each other.

With a placebo effect influencing up to 30% of patients [671], the efficacy of clonidine, veralipride, gabapentine [672] and acupuncture [673] must be compared in prospective, randomised, controlled trials.

6.8.7.1.3 Other systemic side-effects of androgen-deprivation therapy

They are frequent and may lead to significantly increased morbidity or even mortality.

6.8.7.1.3.1 Non-metastatic bone fractures

Due to increased bone turnover and decreased BMD in a time-dependent manner, ADT use is linked to an increased risk of fracture (up to 45% relative risk with long-term ADT [674]). Hip fractures in men are associated with a significant risk of death [675]. A precise evaluation of BMD should be performed by dual emission X-ray absorptiometry (DEXA) before starting long-term ADT. An initial low BMD (T-score < -2.5 or < -1, with other risk

factors) indicates a high risk of subsequent non-metastatic fracture. The WHO FRAX tool (<http://www.shef.ac.uk/FRAX>) should be used to evaluate individual risk. Obesity (increase in body fat mass by up to 10%) and sarcopenia (decrease in lean tissue mass by up to 3%) are common and occur during the first year of ADT [676]. Both changes increase the fracture risk.

- Lifestyle changes before starting long-term androgen-deprivation therapy

Patients should be encouraged to adopt lifestyle changes, e.g. increased physical activity, cessation of smoking, decreased alcohol consumption, and to normalise their body mass index. Calcium and vitamin D supplements should be considered if low values are detected. (Normal values: calcium: 2.2-2.6 nmol/L, vitamin D: 100-160 nmol/L). A daily intake of at least 1200 mg/day of calcium and 1000 UI of vitamin D is useful.

- Hormonal treatment modalities

Bicalutamide monotherapy could be a bone-protective treatment [677, 678], but is limited by its suboptimal efficacy (see Section 6.6 - Metastatic Prostate Cancer - Hormonal Therapy).

The intermittent modality might be associated with less bone impact [589].

- Bisphosphonates

Bisphosphonates increase BMD in the hip and spine by up to 7% in 1 year. The optimal regimen for zoledronic acid remains unclear: quarterly [679] or yearly [680] injections. The question is relevant as the risk of jaw necrosis is both dose- and time-related [681]. A quarterly regimen could be considered for a BMD ≤ 2.5 as a yearly injection is unlikely to provide sufficient protection [682].

In contrast to breast cancer, a significant benefit in OS has only been demonstrated in PCa in a post-hoc analysis for the oral first-generation clodronate with an absolute 8% OS increase after 8 years of follow-up [683]. This benefit has never been observed with more recent bisphosphonates.

- Denosumab (a fully human monoclonal antibody against RANKL)

In M0 patients, Denosumab has been shown to increase the lumbar BMD by 5.6% compared to a 1% decrease in the placebo arm after 2 years, using a 60 mg subcutaneous regimen every 6 months [684]. This was associated with a significant decrease in vertebral fracture risk (1.5% vs 3.9%, $p = 0.006$). The benefits were similar whatever the age ($<$ or $>$ 70 years), the duration or type of ADT, the initial BMD, the patient's weight or the initial BMI. This benefit was not associated with any significant toxicity, e.g. jaw osteonecrosis or delayed healing in vertebral fractures. In M0 patients, with the use of a higher dosage (120 mg every 4 weeks), a delay in bone metastases of 4.2 months has been shown [685] without any impact on OS, and with increased side effects. Therefore, this regimen cannot be recommended.

6.8.7.1.3.2 Metabolic effects

Lipid alterations are common and may occur as early as the first 3 months of treatment [676]. ADT also decreases insulin sensitivity and increases fasting plasma insulin levels, which is a marker of insulin resistance. Once again, exercise is strongly recommended for its protective effect. In diabetic patients, metformin appears to be an attractive option for protection against metabolic effects [686], but there is insufficient data to recommend its use in non-diabetic patients.

Metabolic syndrome is an association of independent cardiovascular disease risk factors, often associated with insulin resistance. The definition requires at least three of the following criteria [687]:

- waist circumference > 102 cm;
- serum triglyceride > 1.7 mmol/L;
- blood pressure $> 130/80$ mmHg or use of medication for hypertension;
- HDL cholesterol < 1 mmol/L;
- glycaemia > 5.6 mmol/L or the use of medication for hyperglycaemia.

The prevalence of a metabolic-like syndrome is higher during ADT compared with men not receiving ADT [688].

6.8.7.1.3.3 Cardiovascular morbidity

Cardiovascular mortality is now the most common cause of death in PCa patients, even exceeding PCa mortality [689]. Several studies showed that ADT, even after only 6 months, was associated with an increased risk of diabetes mellitus, cardiovascular disease, and myocardial infarction [690]. The RTOG 92-02 [691] and 94-08 [396] confirmed an increased cardiovascular risk, unrelated to the duration of ADT and not accompanied by an overall increased cardiovascular mortality. No increase in cardiovascular mortality has been reported in a systematic meta-analysis of trials RTOG 8531, 8610, 9202, EORTC 30891 or EORTC 22863 [692]. However, an increase in cardiovascular mortality has been reported in patients suffering from previous congestive

heart failure or myocardial infarction in a retrospective database analysis [693] or presenting with a metabolic syndrome [694].

It has been suggested that LHRH antagonists might be associated with less cardiovascular morbidity compared to agonists [695]. However, the used methodology does not provide convincing evidence to show a clear superiority of these compounds.

These data resulted in an FDA warning and consensus paper from the American Heart, Cancer Society and Urological Associations [696]. Preventive advice includes non-specific measures: loss of weight, increased exercise, improved nutrition and smoking cessation.

6.8.7.1.3.4 Fatigue

Fatigue often develops as a side-effect of ADT. Regular exercise appears to be the best protective measure [697, 698], with prolonged efficacy [699] and improved specific survival [700].

Anaemia may be a cause of fatigue. Anaemia requires an etiological diagnosis (medullar invasion, mainly inflammatory, renal insufficiency, iron deficiency, chronic bleeding) and individualised treatment. Iron supplementation (using injectable formulations only) must be systematic if deficiency is observed. Regular blood transfusion is required if severe anaemia is present. Erythropoiesis-stimulating agents might be considered in dedicated cases, taking into account the possible increased risk of thrombovascular events [667].

6.8.8 **Comparison of health-related quality of life between treatment modalities**

So far, any comparisons between treatment-related QoL were assessed in non-randomised observational cohorts, with limited follow-up. Only a few trials have directly compared treatment modalities but longer follow-up is needed. When comparing general HRQoL for treatments of clinically localised PCa [631, 701] the differences were limited. Data from longitudinal studies show that surgery and radiotherapy have a greater impact on role functioning and vitality/energy with surgery being associated with increased dysfunction [647]. Most men recovered function by 1 year after treatment.

QoL outcomes have been reported for RP or EBRT [642]. At 5 years after diagnosis, sexual function declined similarly in both groups. Erectile dysfunction was more prevalent in the RP group (79.3% vs 63.5%). Incontinence was reported in 14-16% of RP and 4% of EBRT patients at 5 years. Bowel urgency and painful haemorrhoids were more common in the EBRT group. At 15 years, there were no significant differences between RP and EBRT [34]. RP incurred a significantly higher incidence of urinary incontinence (39-49%) and erectile dysfunction (80-91%) compared with radiotherapy (6-7% and 41-55%, respectively) [649]. Bowel problems (urgency) affected 30-35% of the EBRT group vs. 6-7% of the RP group [649].

Patients treated with LDR brachytherapy had significantly higher urinary function scores at 0-6 months after treatment (84.5%) than patients treated with RP (63.3%) [702]. Urinary bother did not differ significantly (67.7% vs. 67.4%, respectively). Decreased sexual function did not return to pretreatment levels in either group.

Urinary incontinence increased at 2 years after RP, whereas bowel problems and urinary irritation-obstruction occurred after EBRT and LDR brachytherapy [632]. Sexual function deteriorated immediately after surgery and then improved, whereas sexual function continued to slowly decline after EBRT and brachytherapy. There was no change in urinary function and little change in bowel function after 1 year. Patients with bowel dysfunction at 1 year after EBRT may expect modest improvement. Although diarrhoea continues to subside, there is little change in tenesmus and rectal urgency, while rectal bleeding becomes more prevalent.

Three years follow-up confirmed long-term changes in adverse effects, e.g., increased urinary symptoms after EBRT or increased sexual dysfunction after LDR brachytherapy, which tended to reduce any differences between treatments over time [703]. RP caused greater deterioration in urinary incontinence and sexual function, but improved urinary irritative-obstructive symptoms compared with LDR brachytherapy. Treatment differences persisted for up to 3 years [703].

A comparative trial of RP and LDR brachytherapy was closed after 2 years due to poor accrual [704]. For LDR brachytherapy vs. RP, there were no differences in bowel or hormonal domains. The LDR brachytherapy patients scored better for the urinary QoL and sexual domains, and patient satisfaction.

A study in Norway investigated the relationship between urinary, bowel or sexual dysfunction and global QoL in PCa survivors, including untreated patients [638]. The RP group reported more urinary incontinence than other groups, but had the lowest level of urinary irritative-obstructive symptoms. Untreated patients had the highest level of these symptoms. The radiotherapy group reported more intestinal irritation and faecal leakage than the RP and untreated groups. In all groups, poor sexual drive and erectile function were common, with

the RP group reporting the highest prevalence of erectile dysfunction. Irritative-obstructive urinary symptoms and poor sexual drive were independently associated with low global QoL, whereas erectile function and use of medication for erectile dysfunction were not [638].

All typical adverse events (moderate/severe IPSS, urinary incontinence, irritative intestinal symptoms, faecal leakage, poor sexual drive and poor erectile function) were significantly associated with low global QoL in univariate analyses. Low educational level, comorbidity and moderate or high neuroticism were all significantly associated with low global QoL in univariate analyses. No significant associations with global QoL were observed for age, a paired relationship or D'Amico risk group.

LDR brachytherapy and prostate cryoablation were associated with better urinary function and bother scores compared to open RP and laparoscopic and robotic radical prostatectomy in a non-randomised cohort of patients [705]. LDR brachytherapy was associated with higher sexual function and bother scores compared to other treatments. The study used the UCLA-PCI questionnaire, which does not evaluate irritative urinary symptoms, which are often observed after LDR brachytherapy [702]. This may have significantly compromised the results of the HRQoL assessment.

Many men treated for clinically localised PCa experience post-treatment problems that may affect their daily lives. Each patient must decide which side-effect profile is most acceptable when making treatment decisions.

6.8.9 Guidelines on quality of life in prostate cancer management

	LE	GR
Patients with low-risk PCa should be informed that functional outcome of active surveillance is better than for local active treatment.	2	B
Patients should be informed that functional outcome after RALP and open prostatectomy are similar.	2	B
Patients should be informed that long-term (15 years) QoL outcomes of EBRT and RP are similar.	2	B

EBRT = external beam radiation therapy; GR = grade of recommendation; LE = level of evidence; RALP; RP = radical prostatectomy; QoL = quality of life.

6.9 Summary of guidelines for the primary treatment of prostate cancer

EAU risk groups for biochemical recurrence of localised and locally advanced prostate cancer

	Low-risk	Intermediate-risk	High-risk
Definition	PSA < 10 ng/mL and GS < 7 and cT1-2a	PSA 10-20 ng/mL or GS 7 or cT2b	PSA > 20 ng/mL or GS > 7 or cT2c
	Localised		Locally advanced

Primary treatment of prostate cancer			Gr
General comments	Patients suitable for several treatment modalities (active surveillance, surgery, radiotherapy) must have these options discussed with them.		A*
	In patients who are surgical candidates for radical prostatectomy, all approaches (i.e. open, laparoscopic or robotic) are acceptable as no single approach has shown clear superiority in terms of functional or oncological results.		A
	EBRT should be offered in all risk groups of non-metastatic PCa.		A
	IMRT is the recommended modality for definitive treatment of PCa by EBRT.		A
	Treatment	Comment	
Low risk PCa	Watchful waiting	Watchful waiting may be offered to patients not eligible for local curative treatment and those with a short life expectancy.	A
		During watchful waiting, the decision to start non-curative treatment should be based on symptoms and disease progression.	B
	Active surveillance	Active surveillance is an option in patients with the lowest risk of cancer progression: > 10 years life expectancy, cT1/2, PSA ≤ 10 ng/mL, biopsy Gleason score ≤ 6, ≤ 2 positive biopsies, minimal biopsy core involvement (≤ 50% cancer per biopsy).	A

		Follow-up should be based on DRE, PSA and repeat biopsies. The optimal follow-up interval is still unclear.	A
	Radical prostatectomy	In patients with a life expectancy > 10 years, RP should be offered.	A
		Nerve-sparing surgery may be attempted in pre-operatively potent patients with low risk for extracapsular disease (T1c, GS < 7 and PSA < 10 ng/mL, or refer to Partin tables/nomograms).	B
		LND is not indicated in low-risk PCa	A
	Radiotherapy	In low-risk PCa the total dose should be 74 to 78 Gy.	A
		In patients with low-risk PCa, without a previous TURP and with a good IPSS and a prostate volume < 50 mL, LDR brachytherapy is a treatment option.	A
	Cryotherapy, HIFU	In patients who are unfit for surgery or radiotherapy, cryotherapy or HIFU might be an alternative treatment for PCa. The lack of long-term efficacy compared to standard modality has to be discussed with patients.	C
	Focal treatment	Focal therapy of PCa is still in its infancy and cannot be recommended as a therapeutic alternative outside clinical trials.	A
Intermediate risk PCa	Androgen suppression	Unsuitable.	A
	Watchful waiting	Watchful waiting may be offered to patients not eligible for local curative treatment and those with a short life expectancy.	A
	Active surveillance	Not an option.	A
	Radical prostatectomy	In patients with a life expectancy > 10 years, RP should be offered.	A
		Nerve-sparing surgery may be attempted in pre-operatively potent patients with low risk for extracapsular disease (T1c, GS < 7 and PSA < 10 ng/mL, or refer to Partin tables/nomograms).	B
		Multiparametric MRI may help in deciding when to perform nerve-sparing procedures in intermediate- and high-risk disease.	B
		eLND should be performed if the estimated risk for positive lymph nodes exceeds 5%.	B
		Limited LND should not be performed.	A
		In patients with pT3,N0M0 PCa and an undetectable PSA following RP, adjuvant external beam irradiation should be discussed as an option because it improves at least biochemical-free survival.	A
		Patients with pT3,N0M0 PCa and an undetectable PSA following RP should be informed about salvage irradiation as an alternative to adjuvant irradiation when PSA increases.	A
		Adjuvant HT for pN0 is not recommended.	
	Radiotherapy	In intermediate-risk PCa the total dose should be 76-78 Gy, in combination with short-term ADT (4-6 mo).	A
	Androgen suppression monotherapy	No place in asymptomatic patients.	A
High risk PCa	Watchful waiting	High risk localised: Watchful waiting may be offered to patients not eligible for local curative treatment and those with a short life expectancy.	
		High risk locally advanced: In M0 patients unwilling or unable to receive any form of local treatment, a deferred treatment policy using ADT as monotherapy is feasible in asymptomatic patients with a PSA-DT > 12 months and a PSA < 50 ng/mL and non-poorly differentiated tumour.	A
	Active surveillance	Not appropriate.	A
	Radical prostatectomy	NHT before RP is not recommended.	A

		eLND should be performed in high-risk PCa.	A
		Limited LND should not be performed.	A
		High risk localised: In patients with high-risk localised PCa and a life expectancy of > 10 yr, RP should be offered in a multimodality setting.	B
		Nerve-sparing surgery may be attempted in pre-operatively potent patients with low risk for extracapsular disease (refer to Partin tables/nomograms).	B
		Multiparametric MRI may help in deciding when to perform nerve-sparing procedures in intermediate- and high-risk disease.	B
		High risk locally advanced: In highly selected patients with locally advanced PCa (cT3b-T4 N0 or any T N1), RP may be offered in a multimodality setting.	C
		In patients with pT3,N0M0 PCa and an undetectable PSA following RP, adjuvant external beam irradiation should be discussed as an option because it improves at least biochemical-free survival.	A
		Patients with pT3,N0M0 PCa and an undetectable PSA following RP should be informed about salvage irradiation as an alternative to adjuvant irradiation when PSA increases.	A
	Radiotherapy	In patients with high-risk localised PCa, the total dose is 76-78 Gy in combination with long-term ADT (2-3 yr is recommended).	A
		In patients with locally advanced cN0 PCa, radiotherapy must be given in combination with long-term ADT (2-3 yr is recommended).	A
	Androgen suppression monotherapy	Reserved for those unwilling or unable to receive any form of local treatment and either symptomatic or asymptomatic with a PSA-DT < 12 months and a PSA > 50 ng/mL and a poorly differentiated tumour.	A
N1 patients			
cN1	In patients with cN+ PCa, pelvic external irradiation can be given in combination with immediate long-term ADT.		B
pN1 after eLND	Adjuvant ADT is the standard of care for node-positive (pN+) patients.		A
	Adjuvant ADT with additional radiotherapy may have a role.		B
	Expectant management is optional when the patient has undergone eLND and ≤ 2 nodes show microscopic involvement and a PSA < 0.1 ng/mL and absence of extranodal extension.		B
Metastatic PCa	Watchful waiting	In M1 asymptomatic patients, deferred castration should be discussed with a well-informed patient.	B
	Active surveillance	Unsuitable.	A
	Radical prostatectomy	Unsuitable outside clinical trial.	A
	Radiotherapy to the prostate	Unsuitable outside clinical trial.	A
	Androgen suppression	Surgical- or medical castration (LHRH agonist or antagonist).	A
		No recommendation can be made to define the best population for combining castration with upfront Docetaxel.	A
		Castration combined with local treatment / other new hormonal treatments (abiraterone acetate or Enzalutamide) should not be used outside clinical trials.	A
		In M1 asymptomatic patients, immediate castration should be offered to defer progression to a symptomatic stage and prevent serious disease progression-related complications.	A
		In M1 symptomatic patients, immediate castration should be offered to palliate symptoms and reduce the risk for potentially catastrophic sequelae of advanced disease (spinal cord compression, pathological fractures, ureteral obstruction, extraskeletal metastasis).	A

	In M1 patients, short-term administration of anti-androgens is recommended to reduce the risk of the 'flare-up' phenomenon in patients with advanced metastatic disease who are to receive an LHRH agonist.	A
	In M1 patients short-term administration of anti-androgens should be given for some weeks only (starting treatment on the same day as an LHRH analogue is started or for up to 7 days before the first LHRH analogue injection).	A
	In M1 patients, administration of anti-androgens as monotherapy should not be considered.	A
	In asymptomatic M1 patients, intermittent treatment can be offered to highly motivated men, with a major PSA response after the induction period.	B
	Based on the schedules in use in clinical trials, treatment is stopped when the PSA is < 4 ng/mL after 6 to 7 months of treatment. Treatment is resumed when the PSA is > 10-20 ng/mL.	C
	Combined treatment with LHRH agonists and NSAA is recommended.	A
	Antagonists might be an option.	B
Castrate resistant status	Patients should not be started on second-line therapy unless their testosterone serum levels are < 50 ng/dL.	A
	There is no evidence for treatment of non-metastatic CRPC outside a clinical trial.	A
	Patients with mCRPC should be counseled, managed and treated by a multidisciplinary team.	A
	Men treated with maximal androgen blockade should stop the anti-androgen therapy once PSA progression is documented. <i>Comment: Four to six weeks after discontinuation of flutamide or bicalutamide, an eventual anti-androgen withdrawal effect will be apparent.</i>	A
	No clear-cut recommendation can be made for the most effective drug for secondary treatment (i.e. hormone therapy or chemotherapy) as no clear predictive factors exist.	A
	Salvage hormonal treatment using abiraterone acetate is a valid option.	A
	Salvage hormonal treatment using enzalutamide is a valid option.	A
	In patients with metastatic CRPC who are candidates for salvage cytotoxic therapy, docetaxel at 75 mg/m ² every 3 weeks has shown a significant survival benefit.	A
	In patients with relapse following salvage docetaxel chemotherapy, cabazitaxel, abiraterone acetate and enzalutamide are regarded as first-choice options for second-line treatment in mCRPC.	A
	In men with mCRPC and with symptomatic bone metastases, who are ineligible for or progressing after docetaxel, treatment with Ra 223 (alpharadin) has shown a survival benefit.	A
	Bone protective agents may be offered to patients with skeletal metastases (denosumab being superior to zoledronic acid) to prevent osseous complications. However, the benefits must be balanced against the toxicity of these agents, and jaw necrosis in particular must be avoided.	A
	Calcium and vitamin D supplementation must be systematically considered when using either denosumab or bisphosphonates.	A
	In patients with neurological symptoms, spinal surgery or decompressive radiotherapy might be indicated as emergency interventions. High-dose corticosteroids must always be initially considered.	A

A* Upgraded following panel consensus.

ADT = androgen deprivation therapy; DRE = digital rectal examination; EBRT = external beam radiation therapy; HIFU = high-intensity focused ultrasound; LHRH = luteinising-hormone-releasing hormone; LND = (extended) lymph node dissection; mCRPC = metastatic castrate-resistant prostate cancer; MRI = magnetic resonance imaging; NHT = neoadjuvant hormonal therapy; NSAA = non-steroidal anti-androgen; PSA-DT = PSA doubling time; RP = radical prostatectomy; TURP = transurethral resection of the prostate.

Guidelines for the treatment of senior adults (> 70 years of age)

	GR
Senior adults with localised PCa should systematically undergo health status screening	A
Health status screening should be performed using the G8 screening tool	A
Patients with G8 score ≤ 14 should undergo full specialist geriatric evaluation	A
Senior adults can be classified as follows: 1. Fit or healthy older men, should receive standard treatment; 2. Vulnerable patients (reversible impairment) may be given standard treatment after resolution of geriatric problems; 3. Frail patients (irreversible impairment) should receive adapted treatment; 4. Patients who are too sick with terminal illness should receive only symptomatic palliative treatment.	B

Treatment	LE	GR
<i>Localised disease</i>		
Fit and vulnerable senior adults (after status optimisation) with life expectancy > 10 years and high-risk disease should be offered standard treatment.	2b	A
In frail or 'too-sick' patients, immediate ADT should only be used for symptom palliation.	1b	A
Minimally invasive energy-ablative therapies should not be routine in senior adults. These only have a role in selected fit and vulnerable senior adults with intermediate-risk disease.	3	B
<i>Advanced disease (locally advanced / metastatic disease)</i>		
Evaluation of bone mineral status and prevention of osteoporotic fracture are recommended in patients at high-risk of fractures.	2b	A
New chemotherapeutic and hormonal agents can be used in fit and vulnerable adults.	1b	B

DT = doubling time; NHT = neoadjuvant hormonal treatment; GR = grade of recommendation;

IPSS = International Prostatic Symptom Score; LE = level of evidence; PSA = prostate specific antigen; TRUS = transrectal ultrasound; TURP = transurethral resection of the prostate.

6.10 Treatment of PSA-only recurrence after treatment with curative intent

6.10.1 Background

Primary curative procedures such as RP, and RT are well-established therapeutic options in the management of localised PCa. Despite technical improvements, there is still a significant risk of cancer recurrence after therapy. Between 27% and 53% of all patients undergoing RP or RT develop PSA-recurrence (see Sections 6.2 and 6.3). While a rising PSA level universally antedates metastatic progression and prostate-cancer-specific mortality (PCSM), physicians must inform the patient that the natural history of PSA-only recurrence may be prolonged and that a PSA rise is not a surrogate for these survival endpoints. Physicians treating patients with PSA-only recurrence face a difficult set of decisions in attempting to delay the onset of metastatic disease and death while avoiding over-treating patients whose disease may never affect their OS or QoL. It has to be emphasised that the treatment recommendations for these patients should be given after discussion with a multidisciplinary team.

6.10.2 Definitions

6.10.2.1 Definition of biochemical failure

The PSA level that defines treatment failure differs between men who have undergone RP and those who have received RT. However, following RP, there is international consensus that recurrent cancer may be defined by two consecutive PSA values of > 0.2 ng/mL and rising [706]. Although a retrospective analysis including 2,782 men who had undergone RP for clinically localised PCa [707] was used to determine the best PSA cut-off point for defining BCR. Once PSA recurrence was detected, there was a subsequent increase in PSA in 49%, 62%, and 72% of patients with PSA levels of 0.2, 0.3, and 0.4 ng/mL, respectively [707].

After primary RT, with or without short-term hormonal manipulation, the RTOG-ASTRO Phoenix Consensus Conference definition of PSA failure (with an accuracy of > 80%) is any PSA increase ≥ 2 ng/mL higher than the PSA nadir value, regardless of the serum concentration of the nadir [708].

Importantly, patients with PSA-recurrence after RP or primary RT have different risks of subsequent PCSM. Therefore, physicians should carefully interpret BCR endpoints when comparing treatments.

6.10.3 **Natural history of biochemical failure**

Once a PSA relapse has been diagnosed, it is important to determine whether the recurrence has developed at local or distant sites. The risk of subsequent metastases and PCSM may be predicted by the initial clinical factors (e.g. T-category, PSA, biopsy Gleason score). If the patient has undergone RP, the pathological outcomes of the surgery (e.g. pathologic T-category and prostatectomy Gleason score, nodal and margin status) may provide further information. Beyond pre- and posttreatment clinico-pathological factors, PSA kinetics (PSA doubling-time (PSA-DT) and interval to PSA failure) may be used to estimate the risk of metastases and subsequent PCSM.

6.10.3.1 *Post-radical prostatectomy biochemical recurrence*

According to Pound et al. [363], not all patients with BCF after RP develop clinical recurrence. The authors evaluated the follow-up data for 1,997 patients after RP, and only 34% of those with BCF subsequently had a clinical recurrence. These data were confirmed by Boorjian et al. in a study including approximately 2,400 patients; only a minority of those with BCF after RP developed a clinically evident recurrence (22.9%) and only a few died of PCa (5.8%) [709]. Overall, these studies demonstrated a general trend among men with PSA-only recurrence after RP (i.e. 7-40% of relapsing men): for every 100 men treated with RP, approximately 15-30 will develop BCR and 2-6 of those will die of PCa.

Several studies have attempted to identify risk factors for metastases and PCSM in patients experiencing PSA-only recurrence following RP. Compiling the results of several studies, a subgroup with a high risk of metastases and PCSM was characterised by a PSA-DT < 3 months, seminal vesicle invasion (pT3b), specimen Gleason score 8-10, or time to PSA-recurrence < 3 years. Furthermore, a low-risk subgroup was defined as patients with a PSA-recurrence > 3 years following surgery, specimen Gleason score ≤ 7, pathologically organ confined disease or limited extracapsular extension (pT3a), and PSA-DT > 12 months [710-713]. Patients in the high-risk subgroup universally have an exponentially higher risk of developing metastases and dying of PCa. In other words, many patients in the high-risk subgroup likely have micro-metastatic disease or significant local recurrence at the time of PSA-rise, while those in the low-risk subgroup likely have a slow-growing local recurrence only. Indeed, patients in the low-risk subgroup typically respond very well to salvage RT with a high probability of PSA being undetectable [714]. However, it must be stressed that most patients within the low-risk subgroup have an excellent outcome even without any salvage treatment. Therefore, the decision to treat these patients should be made after careful consideration of the pro and cons, taking into account the life expectancy of the patient and his expectations. Patients within the high-risk subgroup need early and aggressive salvage treatment [715]. Trock et al. demonstrated that salvage RT was associated with a significant 3-fold increase in prostate-cancer-specific survival relative to those who received no salvage treatment. The increase in prostate-cancer-specific survival associated with salvage RT was limited to men with a PSA-DT of < 6 months and remained after adjustment for pathological stage and other established prognostic factors. Salvage RT initiated > 2 years after recurrence provided no significant increase in prostate-cancer-specific survival [715].

6.10.3.2 *Post-radiotherapy biochemical recurrence*

Similar to patients experiencing PSA-recurrence after RP, patients with a PSA-rise following RT can be subdivided into prognostic categories. A high-risk subgroup with elevated risk of metastases and PCSM are those patients with a PSA-DT < 3 months, time to biochemical progression < 3 years, biopsy Gleason score 8-10 and clinical stage cT3b-T4. Conversely, patients at low risk of metastases and PCSM are those with a PSA-DT > 15 months, biopsy Gleason score ≤ 7, clinical stage ≤ cT3a and time to biochemical progression > 3 years [712, 716, 717].

Zumsteg et al. have designed a risk score to further subdivide patients who develop PSA recurrence following RT. Those with either 0, 1 or ≥ 2 high-risk factors (PSA-DT < 3 months, time to biochemical progression < 3 years, biopsy Gleason score 8-10 and clinical stage cT3b-T4) have an increased risk of developing metastases and PCSM [717].

Again, the choice of local salvage treatment (salvage RP, salvage cryo, salvage HIFU, salvage brachytherapy) should be guided by the life expectancy and oncological risk profile of each patient, together with the patient's expectations.

6.10.4 **Assessment of metastases**

6.10.4.1 *Bone scan and abdominopelvic computed tomography*

The standard workup to detect PCa metastases usually includes bone scan and abdominopelvic CT. However, because biochemical failure after RP or radiation therapy precedes clinical metastases by 7-8 years on average, the diagnostic yield of usual imaging techniques is poor in asymptomatic patients [718]. In men with

PSA-only relapse after RP, the probability of a positive bone scan is < 5%, when the PSA level is < 7 ng/mL [719, 720]. A PSA doubling time (PSA-DT) < 6 months or a PSA velocity > 0.5 ng/mL/month are predictors of positive bone scan [719, 721].

CT sensitivity for detecting local recurrences or lymph node metastases is low. Only 11-14% of patients with biochemical failure after RP have positive CT [719]. In a series of 132 men with biochemical failure after RP, the mean PSA level and PSA velocity associated with positive CT was 27.4 ng/mL and 1.8 ng/mL/month, respectively [721]. Therefore, bone scan and abdominopelvic CT should only be considered in patients with biochemical failure after RP who have a high baseline PSA (> 10 ng/mL) or high PSA kinetics (PSA-DT < 6 months or PSA velocity > 0.5 ng/mL/month) or in patients with symptoms of bone disease [719].

However, more sensitive methods are needed to detect metastatic patients among candidates for local salvage treatment.

6.10.4.2 Choline and Acetate positron emission tomography (PET)/computed tomography (CT)

¹⁸F-fluorodeoxyglucose (FDG) is of limited value due to low uptake by PCa. In contrast, ¹¹C- or ¹⁸F-Choline and ¹¹C-Acetate have shown promising results in the early detection of local and distant recurrences [240]. However, their accuracy remains difficult to assess because most published studies are retrospective, evaluate heterogeneous populations (often mixing recurrences after various types of primary treatments), use non-standardised definitions of biochemical failure and are limited by the lack of a reliable histological gold standard. Furthermore, results may be reported on a per-patient or a per-lesion basis and may combine the detection of local recurrences and distant metastases [240].

Recent studies report overall sensitivities and specificities of 55-96% and 57-100%, respectively [240, 722-724]. ¹¹C-Choline PET/CT may detect multiple bone metastases in patients showing a single metastasis on bone scan [725] and may be positive for bone metastases in up to 15% of patients with biochemical failure after RP and negative bone scan [726]. The specificity of ¹¹C-Choline PET/CT is also higher than bone scan with less false positive and indeterminate findings [248, 727].

Several studies evaluated ¹¹C-Choline PET/CT in lymph node staging in patients with biochemical failure after primary treatment, using lymph node dissection as the gold standard. They reported conflicting results. One study found a sensitivity of 64%, a specificity of 90%, a positive predictive value of 86% and a negative predictive value of 72% [728]. The main explanation for the low sensitivity was the lack of detection of micrometastases in lymph nodes. In contrast, others found poor specificity with a 30-47% false-positive rate [729-731]. In a meta-analysis of 609 patients with primary or recurrent PCa, the pooled sensitivity and specificity of Choline PET/CT for pelvic lymph node metastases were 62% (95% CI, 51%-66%) and 92% (95% CI, 89%-94%), respectively [242].

Despite these limitations, Choline- or Acetate-PET/CT changed medical management in 28-48% of patients with biochemical failure after primary treatment [732-735].

However, a large body of literature suggests that Choline or Acetate PET/CT sensitivity is strongly dependent on the PSA level and kinetics [240, 722, 724, 736]. In patients with biochemical failure after RP, PET/CT detection rates are only 5-24% when the PSA level is < 1 ng/mL, but rises to 67-100% when the PSA level is > 5 ng/mL. Similarly, PET/CT sensitivity seems much higher when the PSA velocity is high or the PSA-DT is short. In a recent meta-analysis, Choline PET/CT detection rates were 65% (95% CI, 58%-71%) when the PSA-DT was ≤ 6 months, and were 71% (95% CI, 66%-76%) and 77% (95% CI, 71%-82%) when the PSA velocity was > 1 and > 2 ng/mL/year, respectively [722].

Due to its high cost, PET/CT cannot be recommended in all patients with PSA relapse. After RP, the optimal PSA cutoff level seems to be between 1 and 2 ng/mL [724, 736]. It is unclear whether PSA velocity or PSA-DT thresholds can be used to further select groups of patients in whom PET/CT could be recommended.

After RT, the PSA cutoff level is unclear due to the lack of sufficient data and because the PSA level is more difficult to interpret due to the “physiological” amount of measurable PSA produced by the non-tumoural prostate [724]. In a study of 46 patients with PSA relapse after RT or brachytherapy, the ¹⁸F-Choline PET/CT detection rate was 54.5%, 81%, 89% and 100% when the PSA level was 1-2 ng/mL, 2-4 ng/mL, 4-6 ng/mL and > 6 ng/mL, respectively [737]. In another study of 140 patients the ¹¹C-Choline PET/CT detection rate was not influenced by the PSA level, but only by PSA kinetics [738].

6.10.4.3 Other radionuclide techniques

A ¹¹¹In-capromab pendetide scan (ProstaScint™) yielded disappointing results in patients with biochemical failure after RP or radiation therapy [718, 719]. Its use is therefore not recommended.

¹⁸F-Fluoride PET and PET/CT have a higher sensitivity than bone scan in detecting bone metastases [727]. However, ¹⁸F-Fluoride is limited by a relative lack of specificity and by the fact that it does not assess soft-tissue metastases [248].

6.10.4.4 Whole-body and axial magnetic resonance imaging (MRI)

Diffusion-weighted whole-body MRI and the so-called axial MRI (evaluation of the spine and the pelvi-femoral area only) are more sensitive than bone scan and targeted radiographs [252-254] and seem equally effective as ¹¹C-Choline PET/CT [739] in detecting bone metastases in patients with high-risk PCa. Their sensitivity for lymph node metastases remains low, even if it is slightly higher than that of ¹¹C-Choline PET/CT in high-risk patients [244].

However, little is known regarding the accuracy of whole-body or axial MRI in patients with biochemical failure after RP or radiation therapy [740]. Therefore, the role of these techniques in detecting occult bone or lymph node metastases in the case of biochemical failure remains to be assessed.

6.10.4.5 Assessment of local recurrences

6.10.4.5.1 Local recurrence after radical prostatectomy

The precise localisation of the local recurrence by imaging techniques is needed only if histological proof of the recurrence is mandatory before salvage treatment and/or if this localisation could change treatment planning. Transrectal ultrasound is neither sensitive nor specific in detecting local recurrences after RP. Even with TRUS guidance, the sensitivity of anastomotic biopsies remains low: 40-71% for PSA levels > 1 ng/mL and 14-45% for PSA levels < 1 ng/mL [718]. As a consequence, salvage radiation therapy is usually decided on the basis of the BCR, without histological proof of the local recurrence. The dose delivered to the prostatic bed also tends to be uniform as it has not been demonstrated that a focal dose escalation at the site of recurrence improves the outcome. Thus, most patients undergo salvage radiation therapy without local imaging.

Nonetheless, several studies have reported promising results in the detection of local recurrences using MRI, particularly dynamic contrast-enhanced MRI which showed sensitivities and specificities of 84-88% and 89-100%, respectively [741-743]. However, the mean PSA level in these studies was 0.8-1.9 ng/mL, which is higher than the 0.5 ng/mL threshold usually used for salvage therapy. Recently, two studies evaluated mpMRI in patients with PSA level < 0.5 ng/mL. One found a sensitivity of only 13% in men with PSA level < 0.3 ng/mL [744], while the other reported a sensitivity of 86% in patients with PSA level < 0.4 ng/mL [745]. Thus, it remains to be defined whether MRI is able to correctly detect local recurrences in patients with PSA level < 0.5 ng/mL in order to allow a stereotaxic boost to the recurrence site during salvage radiation therapy. Choline or Acetate PET/CT can also detect local recurrences, but are less sensitive than MRI [723, 746].

6.10.4.5.2 Local recurrence after radiation therapy

In patients with biochemical failure after radiation therapy, the biopsy status is a major predictor of outcome, provided the biopsies are obtained 18-24 months after treatment. Given the morbidity of local salvage options, it is thus necessary to obtain histological proof of the local recurrence before treating the patient [718].

TRUS is not reliable in depicting local recurrences after radiation therapy. In contrast, mpMRI has yielded excellent results [718, 747-749] and can be used for biopsy targeting and guiding local salvage treatment. Detection of recurrent cancer is also feasible with Choline and Acetate PET/CT, but PET/CT has poorer spatial resolution than MRI [732, 733, 738, 750].

6.10.4.6 Guidelines for imaging and second-line therapy after treatment with curative intent

Biochemical recurrence (BCR) after RP	LE	GR
In the case of BCR, bone scan and abdominopelvic CT should be performed only in patients with a PSA level > 10 ng/mL, or with high PSA kinetics (PSA-DT < 6 mo or a PSA velocity > 0.5 ng/mL/mo) or in patients with symptoms of bone disease.	3	A
A Choline PET/CT is not recommended in patients with BCR and a PSA-level < 1 ng/mL	3	A
Biochemical recurrence after RT		
In patients with BCR who are candidates for local salvage therapy, prostate mpMRI may be used to localise abnormal areas and guide biopsy.	3	C

BCR = biochemical recurrence; CT = computed tomography; GR = grade of recommendation; LE = level of evidence; mpMRI = multiparametric magnetic resonance imaging; PET = positron emission tomography; PSA-DT = prostate specific antigen doubling time; RP = radical prostatectomy; RT = radiotherapy.

6.10.5 Treatment of PSA-only recurrences

The timing and mode of treatment for PSA-only recurrences after RP or RT are still controversial.

After RP, the therapeutic options are:

- Radiotherapy at least to the prostatic bed;

- (Complete) androgen deprivation (CAD, AD);
- Intermittent androgen deprivation (IAD);
- Observation.

Following RT, the same therapeutic options - except repeat percutaneous RT - may apply in relation to PSA recurrences. In addition, salvage RP, cryotherapy or brachytherapy may be indicated in carefully selected patients.

6.10.5.1 Radiotherapy (Salvage radiotherapy [SRT] - with or without androgen-deprivation therapy for PSA-only recurrence after radical prostatectomy)

Early SRT provides a possibility of cure for patients with an increasing or persistent PSA after RP. More than 60% of patients who are treated before the PSA level rises to > 0.5 ng/mL will achieve an undetectable PSA level again [494, 751-753], providing patients with an ~ 80% chance of being progression-free 5 years later [495]. A retrospective analysis based on 635 patients who underwent RP in 1982-2004, followed up through December 2007, who experienced BCR and/or local recurrence and received no salvage treatment (n = 397) or salvage RT alone (n = 160) within 2 years of BCR, showed that SRT was associated with a threefold increase in the PCa-specific survival relative to those who received no salvage treatment (P < 0.001). Salvage radiotherapy has also been effective in patients with a short PSA-DT [715]. Despite the indication of salvage RT a “wait and see” strategy is an option in patients with a long PSA-DT of more than 12 months [709]. For an overview see Table 6.10.1.

Table 6.10.1: Selected studies on post-prostatectomy salvage radiotherapy (SRT), sorted by pre-salvage radiotherapy (SRT) PSA level.

Hormone suppression treatment (HT) can influence the outcome ‘biochemically no evidence of disease (bNED)’ or ‘progression-free survival’ (PFS). Therefore, data sets without HT are highlighted. To facilitate comparisons, 5-year bNED/PFS read-outs from Kaplan-Meier plots are included.

Reference	Yr	n	HT %	pre-SRT PSA (ng/mL) median	Median dose (Gy)	bNED / PFS yr	5-yr results
Siegmann, et al. [754]	2011	301	0	0.28	66.6 / 70.2	74% (2)	55% vs. 88% @ 66.6 vs. 70.2 Gy
Wiegel, et al. [495]	2009	162	0	0.33	66.6	54% (3.5)	60% vs. 33% @ PSA ≤ 0.5 vs. > 0.5
Goenka, et al. [755]	2011	285	31	0.4	> 70 (72%)	37% (7)	39%
Cremers, et al. [756]	2010	197	0	0.59	63 / 2.25 frct. (88%)	59% (5)	
Bernard, et al. [757]	2010	364	0	0.6	64.8	50% (5)	
Buskirk, et al. [758]	2006	368	15	0.7	64.8	46% (5)	63% vs. 51% @ PSA < 0.5 vs. 0.5-1.0
Pazona, et al. [759]	2005	223	4.5	0.8	63	40/25% (5/10)	42% vs. 30% @ < 1.3 vs. ≥ 1.3
Pisansky, et al. [760]	2000	166	4	0.9	64	46% (5)	61% vs. 36% @ PSA ≤ 1 vs. > 1

bNED/PFS = biochemically no evidence of disease/progression-free survival; HT = hormone suppression treatment; n = number of patients; SRT = salvage radiotherapy.

The addition of HT to SRT (n = 78) was not associated with an additional increase in the CSS compared with SRT alone [715]. So far, adding ADT to SRT has only shown benefit in terms of biochemical PFS after 5 years in retrospective series [755, 762] and in PFS for “high-risk” tumours [761], however data from prospective randomised trials are missing. Results are awaited from recently completed randomised controlled phase III studies: the Radiation Therapy Oncology Group (RTOG-9061) comparing RT + placebo vs. a combination of RT + bicalutamide (150 mg daily) in the postoperative setting and the French GETUG 16 trial, comparing salvage

EBRT with- or without 6 months of ADT. To date there is no recommendation for patients with primary pN0-stage at RP for a combination of SRT plus additional ADT.

6.10.5.1.1 Dose, target volume, toxicity

To date, the optimal salvage RT dose has not been well defined. It should be at least 66 Gy to the prostatic fossa (plus/minus the bed of the seminal vesicles according to the pathological stage after RP) [751]. Similarly, a US guideline panel regarded 64-65 Gy as the minimum dose that should be delivered post RP [763]. However, more recent data suggest that higher total doses can achieve higher rates of biochemical control at 3-5 years [757]. In a systematic review, the pre-SRT PSA level and SRT dose were correlated with BCR, showing that the relapse-free survival decreased by 2.6% per 0.1 ng/mL PSA and improved by 2% per Gy, suggesting that a treatment dose above 70 Gy should be administered at the lowest possible PSA [751, 764, 765].

There have been various attempts to define common outlines for “clinical target volumes” of PCa [766-768] and for organs at risk of normal tissue complications [769]. However, depending on the applied techniques and accepted constraints, a satisfactory consensus has not yet been achieved. The RTOG consensus was achieved considering two PCa cases, one T2c with positive margins at both sides of the apex and one T3b with extracapsular extension at the right base and right seminal vesicle, but with negative margins [766].

In one report on SRT with 66.6-70.2 Gy in 1.8 Gy fractions, only 2.7% of the patients had moderate proctitis or cystitis grade II. Four patients (1.3%) had grade III cystitis. Six out of 301 patients (2%) developed urethral stricture which was not solely attributable to SRT but also resulted from RP alone [752]. In a retrospective cohort of 285 men receiving 3D-CRT (38%) or IMRT (62%) with 66 Gy in 95% of cases, the high-dose subgroup did not show a significant increase in toxicity [755]. In an analysis involving 30 participating centres, a quality assurance programme assessing target volumes, RT techniques (3D-CRT, IMRT, VMAT) and RT doses (64 vs. 70 Gy) it was found that 3D-CRT was applied in nearly half of the centres and was not associated with significantly worse rectum and bladder DVH parameters, for salvage RT using 70 Gy, when compared with IMRT [770].

However, with dose escalation (72 Gy) or up to a median of 76 Gy, the rate of severe side effects especially for the GU-system clearly increases, even with newer planning and treatment techniques [771, 772]. Of note, compared with 3D-CRT, IMRT was associated with a reduction in grade 2 GI toxicity from 10.2 to 1.9% ($P = 0.02$), while RT technique had no differential effect on the relatively high level of GU toxicity (5-yr: 3D-CRT 15.8% vs. IMRT 16.8%) [771]. After a median salvage IMRT dose of 76 Gy, the 5-year risk of grade 2-3 toxicity rose to 22% for GU and 8% for GI symptoms, respectively [772].

6.10.5.1.2 Comparison of adjuvant radiotherapy (ART) and salvage radiotherapy (SRT)

In a case-control analysis, 361 ART patients were compared with 722 non-ART patients, who were selected to match the cases by treatment period, age, pre-RP PSA, tumour stage, Gleason score and surgical margin status. While the 10-year bNED after ART was significantly improved compared with non-ART (63 vs. 45%), there was no difference in OS. In the same study, an SRT cohort of 856 patients who were treated after biochemical relapse (median PSA 0.8 ng/mL) was followed up over a median of 5.9 years. Sixty-three percent of the SRT patients achieved an undetectable PSA after salvage RT and the hazard ratio for local recurrence after salvage RT was 0.13. However, similar to that after ART, no improved OS was seen after salvage RT [773].

The largest retrospective case-matching study to evaluate ART versus early SRT included pT3N0 R0/R1 patients only (HT was excluded), 390 out of 500 observation-plus-early-SRT patients (median pre-SRT PSA was 0.2 ng/mL) were propensity matched with 390 ART patients. Two and five years after surgery, bNED rates were 91% and 78% for ART vs. 93% and 82% after salvage RT, respectively. Subgroup analyses did not yield significant differences for the two approaches. It was concluded that early SRT does not impair PCa control, but clearly helps to reduce overtreatment which is a major issue in ART [774].

Both approaches (ART and SRT) together with the efficacy of neoadjuvant hormone therapy are currently being compared in three prospectively randomised clinical trials: the Medical Research Council (MRC) Radiotherapy and Androgen Deprivation In Combination After Local Surgery (RADICALS) in the United Kingdom, the Trans-Tasman Oncology Group (TROG) Radiotherapy Adjuvant Versus Early Salvage (RAVES), and Groupe d'Etude des Tumeurs Uro-Génitales (GETUG 17).

Decision-making on whether to proceed with adjuvant RT for high risk PCa - pT3-4 pN0 M0 with undetectable PSA after RP, or to postpone RT as an early salvage procedure in the case of biochemical relapse, remains difficult. In everyday practice, the urologist should explain to the patient before RP that adjuvant RT may be administered if the patient has negative prognostic risk factors. Ultimately, the decision on whether to treat requires a multidisciplinary approach that takes into account the optimal timing of RT when it is used and

provide justification when it is not, and this will help the discussion between the physician and the patient.

6.10.5.2 *Hormonal therapy*

Currently there is no available RCT comparing the effect of salvage ADT, although retrospective comparative studies are available. Still, salvage ADT is often used and represents one major practice of ADT use [775].

A retrospective study including 1,352 patients with post-RP PSA recurrence showed that early ADT was associated with a delay to clinical metastases only in patients with a Gleason score > 7 and/or a PSA-DT < 12 months. After a median follow-up after relapse of 3.7 yr, ADT had no impact on the PCa-specific mortality [776].

A multivariate analysis performed by Choueiri et al. [777] showed that whereas salvage ADT in univariate analysis was harmful in the whole patient population, it showed a survival benefit in multivariate analysis correcting for risk factors (logPSA, age, pGS, pT, surgical margins, PSA failure and salvage RT). In a subanalysis of patients where PSA-DT was known, if corrected for the same risk factors plus PSA-DT (< 6 months vs ≥ 6 months), the survival benefit of salvage ADT increased even more with a HR for death of 0.55 (95% CI 0.36-0.82).

In patients initially treated with radiotherapy, Klayton et al [778] showed there was a clinical benefit of ADT versus observation in patients with a PSA-DT < 6 months. At 7 years follow-up, these patients had a significantly better metastases-free survival and disease-specific survival, whilst this was not the case for patients with a PSA-DT ≥ 6 months.

Regarding the timing of salvage ADT, two large comparative studies show no benefit of early vs. late ADT in patients with BCR [377, 779]. After a median of 10-yr follow-up, Siddiqui et al documented that there was no progression-free or disease-specific survival benefit for early ADT. In patients with a PSA ≥ 2 ng/mL, early ADT even showed worse CSS. A recent study based on the CAPSURE database of relapsing patients did not show any 5- and 10-year specific or overall survival difference when comparing immediate and deferred ADT [779]. In the deferred ADT group, patients with a PSA-DT < 12 months were included; again suggesting PSA-DT might be an important risk factor.

If salvage ADT is considered, an intermittent strategy may be appealing as it decreased by almost 60% the amount of drug used. In a large non-inferiority RCT of 1,386 patients primarily treated with radiotherapy [780], intermittent treatment was non-inferior compared to continuous treatment (median OS: 8.8 years (intermittent), and 9.1 years (continuous (HR: 1.02 (0.86 - 1.21)). In the intermittent ADT group, testosterone recovery to the trial-entry threshold occurred in 79% of patients. Intermittent androgen deprivation provided potential benefits with respect to physical function, fatigue, urinary problems, hot flushes, libido, and erectile function. In metastatic patients (see Section 6.8.7), this modality is reserved for responding patients (achieving a PSA at least below 4 ng/mL after 6 to 8 mo of ADT), and treatment is resumed when the PSA is above 10 ng/mL.

In conclusion, not all patients with relapse after primary curative treatment benefit from salvage ADT. A favourable effect is observed in a high-risk group, which may be defined by short PSA-DT and/or tumour characteristics. Intermittent ADT seems non-inferior to continuous hormones.

6.10.5.3 *Observation*

Observation until the development of clinically evident metastatic disease may represent a viable option for patient with low-risk features (PSA-DT > 12 months, time to BCR > 3 years, GS ≤ 7 and stage ≤ T3a) or unfit patients with a life expectancy < 10 years and/or are unwilling to undergo salvage treatment. In these patients, the median actuarial time to the development of metastasis will be 8 years and the median time from metastasis to death will be a further 5 years [363].

6.10.6 **Management of PSA failures after radiation therapy**

Therapeutic options in these patients are ADT or local procedures such as SRP, cryotherapy, interstitial brachytherapy and high-intensity focused US [781-790]. As a general rule, strong recommendations regarding the choice of any of these techniques cannot be made as the available evidence for these treatment options is of (very) low quality. The following is an overview of the most important findings regarding each of these techniques with a proposal for their indications.

6.10.6.1 *Salvage radical prostatectomy (SRP)*

Salvage radical prostatectomy after RT has the longest history and best likelihood of local control relative to other salvage treatments. However, this must be weighed against the possible adverse events, which are increased compared to primary surgery because of the risk of fibrosis and poor wound healing due to radiation.

6.10.6.1.1 Oncological outcomes

In a recent systematic review of the literature, Chade et al. showed that SRP gave 5- and 10-year biochemical recurrence-free survival (BCR-FS) estimates ranging from 47-82% and from 28-53%, respectively. The 10-yr cancer-specific and OS rates ranged from 70-83% and from 54-89%, respectively. The pre-SRP PSA value and prostate biopsy Gleason score were the strongest predictors of the presence of organ-confined disease, progression, and CSS [791].

In most contemporary series, organ-confined disease, negative SMs, and the absence of seminal vesicle and/or lymph node metastases were favorable prognostic indicators associated with a better disease-free survival of approximately 70-80%, in comparison with 40-60% in patients with locally advanced PCa [790].

Table 6.10.2: Oncological results of selected SRP case series, including at least 30 patients

Reference	Yr	n	Median FU (mo)	Pathologic organ confined, %	PSM, %	Lymph node involvement, %	BCR-free probability, %	CSS, %	Time probability, yr
Sanderson, et al. [792]	2006	51	-	25	36	28	47	-	5
Leonardo, et al. [793]	2009	32	35	53	34	0	75	-	3
Heidenreich, et al. [789]	2010	55	23 (2-56)	73	11	20	87	-	2
Chade, et al. [794]	2011	404	55	55	25	16	37	83	10

BCR = biochemical recurrence; FU = follow-up; mo = months; n = number of patients; PSM = positive surgical margin; CSS = cancer-specific survival.

6.10.6.1.2 Morbidity

Compared to primary open RP, SRP is associated with a higher risk of later anastomotic stricture (47% vs 5.8%), urinary retention (25.3% vs 3.5%), urinary fistula (4.1% vs 0.06%), abscess (3.2% vs 0.7%) and rectal injury (9.2% vs 0.6%) [795]. In more recent series, these complications appear to be less common [788, 791]. Functional outcomes are also worse compared to primary surgery, with urinary incontinence (UI) ranging from 21% to 90% and erectile dysfunction in nearly all patients [791].

Table 6.10.3: Perioperative morbidity in selected SRP case series, including at least 30 patients

Reference	Yr	n	Rectal injury (%)	Anastomotic stricture (%)	Clavien 3-5, %	Blood loss, mL, mean, range
Stephenson, et al. [788]	2004	100	15 vs 2*	30	33 vs 13*	-
Ward, et al. [796]	2005	138	5	22	-	-
Sanderson, et al. [792]	2006	51	2	41	6	-
Gotto, et al. [795]	2010	98	9	41	25	-
Heidenreich, et al. [789]	2010	55	2	11	3.6	360 (150-1450)

* SRP performed before vs after 1993.

n = number of patients; SRP = salvage radical prostatectomy.

6.10.6.2 Summary of salvage radical prostatectomy

In general, SRP should be considered only for patients with low comorbidity, a life expectancy of at least 10 years, a pre-SRT PSA < 10 ng/mL and biopsy Gleason score ≤ 7, no lymph node involvement pre-SRT, and whose initial clinical staging was T1 or T2 [791].

6.10.7 Salvage cryoablation of the prostate

6.10.7.1 Oncological outcomes

In cases in which RT fails, salvage cryoablation of the prostate (SCAP) has been proposed as an alternative to SRP, as it has a potentially lower risk of morbidity and equal efficacy. However, the very few studies available have shown disappointing results. In a review of the use of SCAP for recurrent cancer after RT, the 5-year BDFS estimates ranged from 50-70%. A durable response can be achieved in ~50% of patients with a pre-SCAP PSA < 10 ng/mL [797]. In a multicentre study reporting the current outcome of SCAP in 279 patients, the 5-year biochemical recurrence-free survival (BCR-FS) estimate according to the Phoenix criteria was 54.5 ± 4.9%. Positive biopsies were observed in 15/46 patients (32.6%) who underwent prostate biopsy after SCAP [798].

A case-matched control study comparing SRP and SCAP was performed in men with recurrent PCa after RT. The authors compared the oncological outcomes of the two salvage treatment options after mean follow-up periods of 7.8 (SRP group) and 5.5 years (SCAP group). The 5-year BCR-FS was 61% following SRP, significantly better than the 21% detected after SCAP. The 5-year OS was also significantly higher in the SRP group (95% vs. 85%) [799].

Table 6.10.4: Oncological results of selected SCAP case series, including at least 50 patients

Reference	Yr	n	Median FU (mo)	BCR-free probability, %	Time probability, yr	Definition of failure
Pisters, et al. [800]	1997	150	17	44	-	Nadir + 0.2
Bahn, et al. [801]	2003	59	82	59	7	PSA > 0.5
Ismail, et al. [797]	2007	100	33	73 (low risk)	5	ASTRO
Pisters, et al. [798]	2008	279	22	58	5	ASTRO and Phoenix
Williams, et al. [802]	2011	187	7.46 yr	39	10	Nadir +2
Spiess, et al. [803]	2010	450	40.8	34	-	PSA > 0.5

BCR = biochemical recurrence; FU = follow-up; mo = months; n = number of patients.

6.10.7.2 Morbidity

According to Cespedes et al. [804], the risks of urinary incontinence and erectile dysfunction at least 12 months after SCAP were as high as 28% and 90%, respectively. In addition, 8-40% of patients reported persistent rectal pain, and an additional 4% of patients underwent surgical procedures for the management of treatment-associated complications. In a recent study by Pisters et al, the UI rate was 4.4%. The rectal fistulae rate was 1.2%, and 3.2% of patients required transurethral resection of the prostate (TURP) for removal of sloughed tissue [798]. With the use of third-generation technology, complications such as UI and obstruction/retention have significantly decreased during the last decade (see Table 6.10.5) [805].

Table 6.10.5: Perioperative morbidity, erectile function and urinary incontinence in selected SCAP case series, including at least 50 patients

Reference	Yr	n	Incontinence, %	Obstruction/Retention, %	Rectourethral fistula, %	ED, %
Pisters [800]	1997	150	73	67	1	72
Bahn [801]	2003	59	8	-	3.4	-
Ismail [797]	2007	100	13	4	1	-
Pisters [798]	2008	279	4.4	3.2	1.2	-
Ahmad [806]	2013	283	12	7	1.8	83

ED = erectile dysfunction; n = number of patients.

6.10.7.3 Summary of salvage cryoablation of the prostate

In general, SCAP should be considered only for patients with low comorbidity, a life expectancy of at least 10 years, an initial organ-confined PCa cT1c to cT2, initial Gleason score ≤ 7, a pre-salvage PSA-DT ≥ 16 months and a pre-salvage PSA < 10 ng/mL.

6.10.8 Salvage brachytherapy for radiotherapy failure

Following local recurrence after previous definitive RT there is no indication for external beam salvage RT as

the total dose is limited and therefore the chance of cure is low. For carefully selected patients with primary localised PCa and histologically proven local recurrence, high- or low-dose rate (H/LDR) brachytherapy remain effective treatment options with an acceptable toxicity profile [807-809]. However, the published series are relatively small, therefore this treatment should be offered in experienced centres only. Fifty-two patients were treated at the Scripps Clinic with HDR-brachytherapy over a period of nine years [807]. With a median follow-up of 60 months the 5-year biochemical control was 51% and only 2% grade 3 GU toxicities were reported. Comparable with these data, 42 patients were treated in a phase-II-trial at MSCCC in New York [810]. Of note, the median pre-treatment dose was 81 Gy given with IMRT and the prescription HDR-dose of 32 Gy was delivered in four fractions over 30 hours. The biochemical relapse-free survival after 5 years was 69% (median follow-up 36 months). Grade 2 late side effects were seen in 15% and one patient developed Grade 3 incontinence. However, older data with higher rates of side effects have been reported [811].

Using LDR-brachytherapy with 103Pd (palladium), long-term outcome was reported in 37 patients with a median follow-up of 86 months [114]. The biochemical control rate after 10 years was 54%. However, the crude rate of \geq grade 2 toxicity was 46% and \geq grade 3 toxicity was 11%. These side effects were comparable with a series of 31 patients treated with salvage 125I brachytherapy in the Netherlands. Therefore, in these small series, late side effects seem to be lower with HDR-brachytherapy [812].

In conclusion, freedom from BCR after salvage HDR- and LDR-brachytherapy is promising and the rate of severe side effects in experienced centres seem to be acceptable. Therefore salvage brachytherapy remains a treatment option for selected patients with histologically proven local recurrence after RT.

6.10.9 **Salvage High-intensity focused ultrasound (HIFU)**

6.10.9.1 *Oncological outcomes*

Salvage HIFU has more recently emerged as an alternative thermal ablation option for radiation-recurrent PCa. Most of the data were generated by one high-volume centre. Median follow-up was very short, and outcome measures were non-standardised.

Table 6.10.6: Oncological results of selected salvage HIFU case series, including at least 20 patients

Reference	Yr	n	Median FU (mo)	BCR-free probability, %	Negative biopsy rate
Colombel, et al. [813]	2006	224	15-18	-	80
Gelet, et al. [814]	2000				
Gelet, et al. [815][121]	2004				
Uchida, et al. [816]	2011	22	24	59 (Phoenix) (24 mo)	92 (only 12 biopsied)
Berge, et al. [817]	2011	46	9	60.9 (9 mo)	

FU = follow-up; mo = months; n = number of patients.

6.10.9.2 *Morbidity*

Again, most of the data were generated by one high-volume HIFU centre. Important complication rates were mentioned and are at least comparable to other salvage treatment options.

6.10.9.3 *Summary of salvage high-intensity focused ultrasound (HIFU)*

There is a paucity of data which prohibits any recommendation regarding the indications for salvage HIFU.

6.10.10 **Observation**

Patients who have signs of only local recurrence (i.e., low-risk patients with late recurrence and a slow PSA rise) who do not wish to undergo second-line curative options are best managed by observation alone. A retrospective cohort analysis of HT vs. watchful waiting in 248 men with PSA failure after RT showed no advantage for HT in the subgroup of men with a PSA-DT of > 12 months after RT. The 5-year metastasis-free survival rate was 88% with hormone therapy versus 92% with watchful waiting ($p = 0.74$) [818].

6.10.11 Guidelines for imaging and second-line therapy after treatment with curative intent

Local salvage treatment	LE	GR
Biochemical recurrence (BCR) after RP		
For patients with a PSA rise from the undetectable range and favourable prognostic factors (\leq pT3a, time to BCR > 3 yr, PSA-DT > 12 mo, Gleason score \leq 7) surveillance and possibly delayed salvage RT (SRT) may be offered.	3	B
Patients with a PSA rise from the undetectable range should be treated with SRT. The total dose of SRT should be at least 66 Gy and should be given early (PSA < 0.5 ng/mL).	2	A
Biochemical recurrence (BCR) after RT		
Selected patients with localised PCa at primary treatment and histologically proven local recurrence should be treated with salvage RP (SRP).	3	B
Due to the increased rate of side effects, SRP should be performed in experienced centres.	3	A
High intensity focused ultrasound (HIFU), cryosurgical ablation and salvage brachytherapy are treatment options for patients without evidence of metastasis and with histologically proven local recurrence. Patients must be informed about the experimental nature of these approaches.	3	B
Systemic salvage treatment		
In asymptomatic men with BCR, ADT should not be given routinely.	3	A
Patients with a PSA-DT > 12 mo, should not receive ADT.	3	B
If salvage ADT (post-primary RT) is started, intermittent therapy should be considered in responding patients.	1b	A

ADT = androgen-deprivation therapy; BCR = biochemical recurrence; GR = grade of recommendation; LE = level of evidence; PSA-DT = prostate-specific antigen doubling time; RT = radiotherapy; SRP = salvage radical prostatectomy.

6.11 Treatment: Castration-resistant prostate cancer (CRPC)

6.11.1 Background

Our knowledge of the mechanisms involved in the development of castration-resistant prostate cancer (CRPC), remains incomplete [819, 820]. An alteration in normal androgen signaling is thought to be central to the pathogenesis of CRPC [821]. It is mediated through two main, overlapping, mechanisms. These are androgen-receptor (AR)-independent and AR-dependent.

6.11.2 Definition of progressing prostate cancer after castration

Table 6.11.1: Definition of CRPC

Castrate serum testosterone < 50 ng/dL or 1.7 nmol/L plus either;
Biochemical progression: Three consecutive rises in PSA 1 week apart resulting in two 50% increases over the nadir, with PSA > 2 ng/mL or
Radiological progression: The appearance of two or more new bone lesions on bone scan or enlargement of a soft tissue lesion using RECIST (Response Evaluation Criteria in Solid Tumours) [822].
Symptomatic progression alone must be questioned and is not sufficient to diagnose CRPC.

Frequent post-treatment PSA surveillance has resulted in earlier detection of progression [823]. In such patients occult micro-metastasis might exist, but are usually undetectable using conventional methods [824]. Although 33% will develop bone metastases within 2 years [825], there are no available studies suggesting a benefit for treatment.

In men with CRPC and no detectable clinical metastases, baseline PSA level, PSA velocity and PSA doubling time have been associated with time to first bone metastasis, bone metastasis-free and overall survival [825, 826]. These factors may be used when deciding which patients should be evaluated for metastatic disease. A consensus statement by the Prostate Cancer Radiographic Assessments for Detection of Advanced Recurrence (RADAR) group [827] suggested a bone scan when the PSA reached 2 ng/mL and if this was negative it should be repeated when the PSA reached 5 ng/mL and again after every doubling of the PSA based on PSA testing every 3 months.

The rest of this chapter focuses on management of men with proven metastatic CRPC (mCRPC)

6.11.3 Assessing treatment outcome in castration-resistant PCa (CRPC)

Precise quantification of the effect of treatments on metastatic bone disease is difficult to quantify and rarely used in clinical practice. Improvements in QoL, progression-free survival and prostate-cancer-specific survival are all used, but the gold standard remains OS [828].

6.11.3.1 PSA level as marker of response

Many contemporary studies use PSA as a marker of response, even though there is no consensus about the magnitude and duration of a decline in PSA level. Although PSA is used as a rapid screening tool to test the activity of new agents, there is conflicting evidence about the role of PSA as a surrogate marker. Trials of the vaccines sipuleucel-T (Provenge) [829] and TRICOM (PROSTVAC) [830] have demonstrated a significant OS benefit without any PSA change, raising questions about the value of PSA response for non-hormonal non-cytotoxic drugs [831]. In addition, wide fluctuations have been seen in PSA values due to a transient effect of drugs on PSA production. The effect of drugs on PSA expression should be considered when interpreting PSA response data, which should be viewed together with other clinical data [832-835]. Nevertheless, it has been shown reproducibly that > 30% PSA decline following therapy carries a significant survival advantage [836, 837]. An improved PSA response was also associated with prolonged survival in the TAX 327 study, with a median survival of 33 months when the PSA was normalised (< 4 ng/mL) vs. 15.8 months for an abnormal PSA.

6.11.4 Androgen deprivation in castration-resistant PCa

Eventually men with PCa show evidence of disease progression despite castration. In this situation continued testicular androgen suppression in CRPC is debatable [838].

These data have been challenged by two trials that showed only a marginal survival benefit for patients remaining on LHRH analogues during second- and third-line therapies [839, 840]. However, in the absence of prospective data, the modest potential benefits of a continuing castration outweigh the minimal risk of treatment. In addition, all subsequent treatments have been studied in men with ongoing androgen suppression and therefore it should be continued indefinitely in these patients.

Table 6.11.2: Randomised phase III controlled trials - first-line treatment of mCRPC*

Author	Year	Intervention (N)	Comparison (N)	Selection criteria	Main outcomes
DOCETAXEL					
SWOG 99-19 [841]	2004	Docetaxel/EMP, every 3 weeks, 60 mg/m ² , EMP 3 x 280 mg/day	Mitoxantrone, every 3 weeks, 12 mg/m ² prednisone 5 mg BID		OS: 17.52 vs. 15.6 mo. PFS: 6.3 vs. 3.2 mo.
TAX 327 [842]	2004	Docetaxel, every 3 weeks, 75 mg/m ² prednisone 5 mg BID or Docetaxel, weekly, 30 mg/m ² prednisone 5 mg BID	Mitoxantrone, every 3 weeks, 12 mg/m ² , Prednisone 5 mg BID		OS: 18.91 for 3 weekly vs. 17.4 mo for weekly and 16.5 in the control group.
ABIRATERONE					
COU-AA-302 Ryan [843, 844]	2013	Abiraterone + Prednisone (546)	Placebo + Prednisone (542)	No previous docetaxel. ECOG 0-1. PSA or radiographic progression. No or mild symptoms. No visceral metastases.	OS: 34.7 vs. 30.3 mo (p= 0.0027). FU: 49.2 mo. PFS: 16.5 vs. 8.3 mo. P < 0.0001) (p = Main side effects outcomes: 48% vs. 42% grade 3-4.

ENZALUTAMIDE					
PREVAIL Beer [845]	2014	Enzalutamide (872)	Placebo (845)	No previous docetaxel. ECOG 0-1. PSA or radiographic progression. No or mild symptoms 10% had visceral metastases	<u>OS</u> : 32.4 vs 30.2 mo (p < 0.001). FU: 22 mo. <u>PFS</u> : median not reached vs 3.9 mo (p < 0.001) <u>Main side effects outcomes</u> : Hypertension, fatigue and hot flush
SIPULEUCEL-T					
Kantoff [830]	2010	Sipuleucel-T (341)	Placebo (171)	Some with previous docetaxel. ECOG 0-1. Asymptomatic or minimally symptomatic.	<u>OS</u> : 25.8 vs. 21.7 mo (p.0.03). FU: 34.1 mo. <u>PFS</u> : 3.7 vs 3.6 mo. <u>Main side effects outcomes</u> : 31.7% vs. 35.1%.
Small [829]	2006	Sipuleucel-T (82)	Placebo (45)	ECOG 0-1. No visceral metastases. No bone or cancer pain. No corticosteroids.	<u>OS</u> : 25.9 vs. 21.4 mo (p. 0.01). FU: 36 mo. <u>PFS</u> : 11.7 vs. 10.0 weeks. <u>Main side effects outcomes</u> : 31.1% vs. 29.3% grade 3, 24.45% both groups grade 4.

ECOG = Eastern Cooperative Oncology Group; EMP = estramustine; FU = follow-up; PFS = progression-free survival; OS = overall survival.

6.11.5 Hormonal drugs targeting the endocrine pathways in the pre-docetaxel space

6.11.5.1 Abiraterone

The use of abiraterone in the pre-docetaxel setting was evaluated in the large phase III trial COU-AA-302, in which 1,088 chemo-naïve mCRPC patients were randomised to abiraterone acetate and placebo, both combined with prednisone [843]. Patients were mCRPC, Eastern Cooperative Oncology Group (ECOG) performance status 0 or 1 and were asymptomatic or mildly symptomatic. The study had two joint primary end-points: OS and radiographic PFS. The results reported are from the second preplanned interim analysis. After a median follow-up of 49.2 months, there was significant radiological PFS (median 16.5 vs. 8.2 months, HR: 0.52, p < 0.001) and the trial was unblinded. At that point there was a trend to improved OS, which with further follow-up has become significant [846]. With a median follow-up of 49.4 months OS was 34.7 vs 30.3 months (HR = 0.80, (CI 0.69-0.93) p = 0.0027). All the subgroup analyses and secondary end-points consistently favoured the abiraterone arm. Side effects related to mineralocorticoids and liver function were more frequent with abiraterone, but mostly grade 1/2.

6.11.5.2 Enzalutamide

The Enzalutamide, phase III trial (PREVAIL) has also been unblinded early [845]. In a similar chemo-naïve population of 1717 men this also showed a significant improvement in time to radiological progression (HR 0.186 (CI 0.15-0.23) p < 0.0001) and a marked delay in the initiation of chemotherapy (HR 0.35) with 78% of men seeing at least a 50% decrease in PSA. This also showed statistical improvement in OS (HR 0.706 (CI 0.6-0.84) p < 0.001). The most common clinically relevant adverse events were fatigue and hypertension.

6.11.6 Non-hormonal therapy

6.11.6.1 Docetaxel regimen

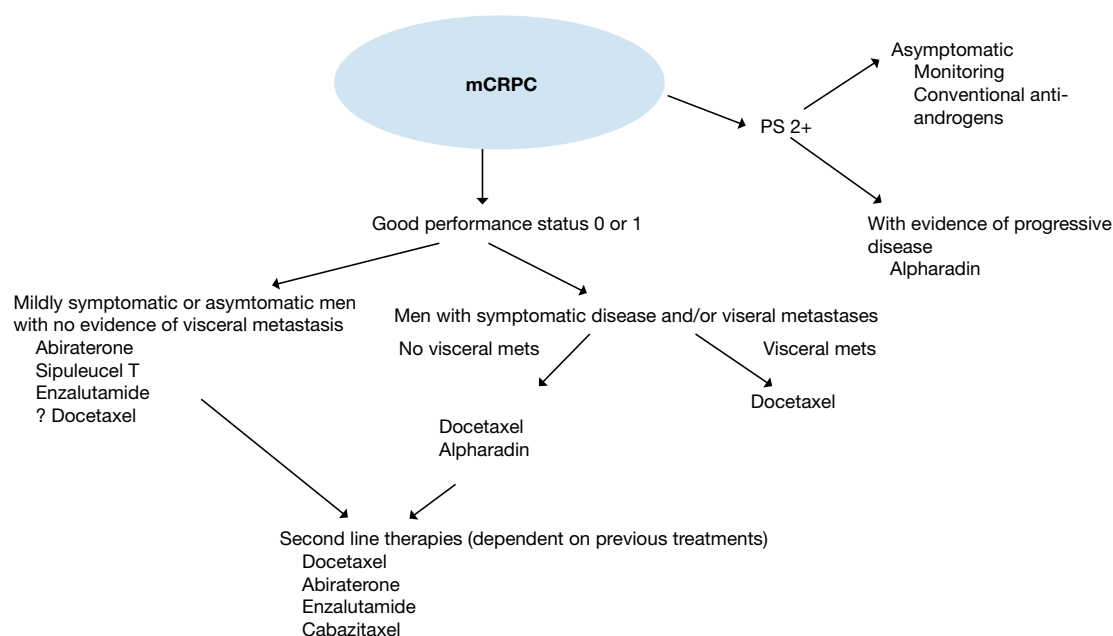

A significant improvement in median survival of 2-2.5 months occurred with docetaxel-based chemotherapy compared to mitoxantrone + prednisone therapy [841, 842]. The standard for first-line cytotoxic chemotherapy is docetaxel using the same regimen as in the TAX 327 trial, that is, 75 mg/m² 3 weekly combined with prednisone 5 mg BID, up to 10 cycles, and palliation is the main target.

The patients considered for docetaxel represent a heterogeneous population. Several poor prognostic factors have been described, such as a PSA level > 114 ng/mL, PSA-DT < 55 days, or the presence of visceral metastases [847]. A better risk group definition has recently been presented, based on the TAX 327 study cohort. The predictive factors were visceral metastases, pain, anaemia (Hb < 13 g/dL), bone scan progression, and prior estramustine before docetaxel. Patients were categorised into three risk groups: low risk (0 or 1 factor), intermediate (2 factors) and high risk (3 or 4 factors), leading to three different lengths of median OS: 25.7, 18.7 and 12.8 months, respectively [848]. In addition, two independent studies have suggested that improved survival can be predicted by C-reactive protein (CRP) levels < 8 mg/L (HR, 2.96) [849, 850]. Age by itself is not a contraindication to docetaxel [851].

6.11.6.2 Vaccine

In 2010, a phase III trial of Sipuleucel T showed a survival benefit in 512 CRPC patients [626]. This was the first time that a PCa vaccine had shown a benefit and led to FDA and EMA approval. Sipuleucel T is an active cellular immunotherapy agent consisting of autologous peripheral blood mononuclear cells, activated in vitro by a recombinant fusion protein comprising prostatic acid phosphatase fused to granulocyte-macrophage colony-stimulating factor, which is an immune-cell activator. In the above trial, patients with metastatic CRPC, with PSA > 5 ng/mL, castrate testosterone level, and no visceral metastases, were randomised to three infusions 2 weeks apart with Sipuleucel T or placebo. The main objective was OS. After a median follow-up of 34 months, the median survival was 25.8 months in the Sipuleucel T group compared to 21.7 months in the placebo group, leading to a significant HR of 0.78 (P = 0.03). Surprisingly, no PSA decline was observed and PFS was equivalent in both arms (14 weeks). The overall tolerance was acceptable, with more cytokine-related adverse events in the Sipuleucel T group, but the same grade 3-4 in both arms. Uptake of Sipuleucel T has been affected by access, cost and questions of timing.

Figure 6.11.1: Flowchart of the potential therapeutic options after PSA progression following initial hormonal therapy

The timing of second-line treatment remains unclear in metastatic CRPC although it is clearly advisable to start immediately in men with symptomatic metastatic disease. As the number of effective treatments available increases and without head to head trials or data assessing the effectiveness of different sequencing options it is not clear how to choose the first “second-line” treatment. In the absence of other data, the inclusion criteria from licensing trials have been used to prioritise treatment sequencing.

Eastern Cooperative Oncology group performance status was used to stratify patients. Generally

men with a performance status of 0-1 are likely to tolerate treatments and those with performance status of 2 or more are less likely to benefit. However, it is important that treatment decisions are individualised and in particular where symptoms related to disease progression are determining performance status it may be appropriate to trial novel treatments in order to see if response is accompanied by improvement in PS.

6.11.7 **Salvage treatment after first-line docetaxel**

All patients who receive docetaxel-based chemotherapy for CRPC will progress, thus, there have been many clinical trials investigating the role of salvage chemotherapy. Several groups have used second-line intermittent docetaxel re-treatment in patients who had clearly responded to first-line docetaxel. In general, a PSA response can be achieved in about 60% of patients with a median time to progression of about 6 months, while treatment-associated toxicity is minimal and similar to that of first-line docetaxel [852, 853].

Available treatments and the setting tested are presented in Table 6.11.3.

Table 6.11.3: Randomised phase III controlled trials - second-line treatment of mCRPC*

Author	Year	Intervention (N)	Comparison (N)	Selection criteria	Main outcomes
ABIRATERONE					
Fizazi [625]	2012	Abiraterone + Prednisone (797)	Placebo + Prednisone (398)	Previous docetaxel. ECOG 0-2. PSA or radiographic progression.	Overall survival: 15.8 vs. 11.2 mo (p < 0.0001). FU: 20.2 mo. Progression-free survival: 5.6 vs. 3.6 mo. Main side effects outcomes: Similar.
de Bono [566]	2011				Overall survival: 14.8 vs. 10.9 mo (p < 0.001). FU: 12.8 mo. Progression-free survival: 5.6 vs. 3.6 mo. Main side effects outcomes: More mineralocorticoid adverse events with abiraterone.
ALPHARADIN					
Parker [854]	2013	Alpharadin (614)	Placebo (307)	Previous or no previous docetaxel. ECOG 0-2. Two or more bone metastases. No visceral metastases.	Overall survival: 14.9 vs. 11.3 mo (p 0.002). FU: Interim analysis. Progression-free survival: 3.6 vs. 3.4 mo (PSA-progression). Main side effects outcomes: 56% vs. 62% grade 3-4.
CABAZITAXEL					
Bahl [628]	2013	Cabazitaxel + Prednisone (378)	Mitoxantrone + Prednisone (377)	Previous docetaxel. ECOG 0-2.	Overall survival: 318/378 vs. 346/377 events (odds ratio 2.11; 95% CI 1.33-3.33). FU: 2 years. Progression-free survival: - Main side effects outcomes: Similar.
deBono [624]	2010 check				Overall survival: 15.1 vs. 12.7 mo (p < 0.0001). FU: 12.8 mo. Progression-free survival: 2.8 vs. 1.4 mos. Main side effects outcomes: 82% vs. 58% neutropenia.

ENZALUTAMIDE					
Scher [567]	2012	Enzalutamide (800)	Placebo (399)	Previous docetaxel. ECOG 0-2.	<p><u>Overall survival:</u> 18.4 vs. 13.6 mo (p < 0.001). FU: 14.4 mo.</p> <p><u>Progression-free survival:</u> 8.3 vs 2.9 mo.</p> <p><u>Main side effects outcomes:</u> 45.3% vs. 53.1% grade 3-4.</p>

**Only studies reporting survival outcomes have been included.*

6.11.7.1 Cabazitaxel

Cabazitaxel is a taxane derivative with some significant differences compared to docetaxel. Positive results have been published from a large prospective, randomised, phase III trial (TROPIC trial) comparing cabazitaxel + prednisone vs. mitoxantrone + prednisone in 755 patients with CRPC, who had progressed after or during docetaxel-based chemotherapy [624]. Patients received a maximum of 10 cycles of cabazitaxel (25 mg/m²) or mitoxantrone (12 mg/m²) plus prednisone (10 mg/day), respectively. Overall survival was the primary end-point and PFS, treatment response and safety were secondary end-points. An OS benefit (15.1 vs. 12.7 months p < 0.0001) was observed in the cabazitaxel arm. There was also a significant improvement in PFS (2.8 vs. 1.4 months, p < 0.0001), objective response rate according to RECIST criteria (14.4% vs. 4.4%, p < 0.005), and PSA response rate (39.2% vs. 17.8%, p < 0.0002). Treatment-associated WHO grade 3/4 side effects developed significantly more often in the cabazitaxel arm, particularly haematological (68.2% vs. 47.3%, p < 0.0002) and non-haematological (57.4% vs. 39.8%, p < 0.0002) toxicity [628]. This drug should be administered by physicians with expertise in handling neutropenia and sepsis, with granulocyte colony-stimulating factor administered prophylactically in the high-risk patient population.

6.11.7.2 Abiraterone acetate

Positive preliminary results of the large phase III COU-AA-301 trial were reported after a median follow-up of 12.8 months [566] and the final results have been reported more recently [625]. A total of 1,195 patients with metastatic CRPC were randomised in a 1/1 fashion to abiraterone acetate or placebo. All patients had progressive disease based on the PCWG2 criteria after docetaxel therapy (with a maximum of two previous chemotherapeutic regimens). The primary end-point was OS, with a planned HR of 0.8 in favour of abiraterone. After a median follow-up of 20.2 months, the median survival in the abiraterone group was 15.8 months compared to 11.2 months in the placebo arm (HR: 0.74, p < 0.001). The benefit was observed irrespective of age, baseline pain intensity, and type of progression. All the secondary objectives were in favour of abiraterone (PSA, radiologic tissue response, time to PSA or objective progression). The incidence of the most common grade 3/4 side effects did not differ significantly between both arms, but mineralocorticoid-related side effects were more frequent in the abiraterone group, mainly grade 1/2 (fluid retention, oedema or hypokalaemia). The longer follow-up did not lead to an unexpected increased in toxicity compared to the preliminary analysis.

6.11.7.3 Enzalutamide

The planned preliminary analysis of the AFFIRM study was published in 2012 [567]. This trial randomised 1,199 patients with metastatic CRPC in a 2/1 fashion to enzalutamide or placebo. The patients had progressed after docetaxel treatment, according to the PCWG2 criteria. Corticosteroids were not mandatory, but could be prescribed, and were therefore received by 30% of the population. The primary end-point was OS, with an expected HR benefit of 0.76 in favour of enzalutamide. After a median follow-up of 14.4 months, the median survival in the enzalutamide group was 18.4 months compared to 13.6 months in the placebo arm (HR: 0.63, p < 0.001). This led to the recommendation that the study be halted and unblinded. The benefit was observed irrespective of age, baseline pain intensity, and type of progression. All the secondary objectives were in favour of enzalutamide (PSA, soft tissue response, QoL, time to PSA or objective progression). No difference in terms of side effects were observed in the 2 groups, with a lower incidence of grade 3-4 side effects in the enzalutamide arm. There was a 0.6% incidence of seizures in the enzalutamide group compared to none in the placebo arm mainly seen in patients with predisposing conditions.

As of today, the choice between third-line hormonal treatment (using enzalutamide or abiraterone) or second-line chemotherapy (cabazitaxel) remains unclear with no clear decision-making findings published. Clinical/biological factors guiding treatment decision are urgently awaited. The optimal sequencing of drugs is not currently known. The cost of each drug will be a major challenge to public health.

6.11.8 Bone targeted therapies in metastatic castration-resistant PCa

CRPC is usually a debilitating disease, often affecting the elderly male. A multidisciplinary approach is often

required with input from medical oncologists, radiation oncologists, urologists, nurses, psychologists and social workers [855]. Critical issues of palliation must be addressed when considering additional systemic treatment, including management of pain, constipation, anorexia, nausea, fatigue and depression, which often occur.

6.11.8.1 Common complications due to bone metastases

Common complications due to bone metastases include bone pain, vertebral collapse or deformity, pathological fractures and spinal cord compression. Cementation is an effective treatment for painful spinal fracture, whatever its origin, clearly improving both pain and QoL [856]. However, it is still important to offer standard palliative surgery, which can be effective for managing osteoblastic metastases [857, 858]. Impending spinal cord compression is an emergency. It must be recognised early and patients should be educated to recognise the warning signs. Once suspected, high-dose corticosteroids must be given and MRI performed as soon as possible. A systematic neurosurgery consultation should be planned to discuss a possible decompression, followed by external beam irradiation [859]. Otherwise, external beam radiotherapy, with or without systemic therapy, is the treatment of choice.

6.11.8.2 Painful bone metastases

Most patients with CRPC have painful bone metastases. External beam radiotherapy is highly effective [860], even as a single fraction [861].

6.11.8.2.1 Radium 223

The only bone-specific drug that is associated with a survival benefit is alfaradin, a radium 223 α -emitter. In a large phase III trial (ALSYMPCA), 921 patients with symptomatic CRPC, who failed or were unfit for docetaxel therapy, were randomised to six injections of 50 kBq/kg alfaradin or placebo. The primary end-point was OS. Alfaradin significantly improved OS by 3.6 months (HR = 0.70; $p < 0.001$) [854]. It was also associated with prolonged time to first skeletal event, improvement in pain scores and improvement in QoL. The associated toxicity was minimal, especially haematologic toxicity, and did not differ significantly from that in the placebo arm [854].

6.11.8.2.2 Bisphosphonates

Bisphosphonates have been used to inhibit osteoclast-mediated bone resorption in CRPC and have proven to be highly effective in reducing bone pain. 643 patients who had CRPC [862] with bone metastases were randomised to receive zoledronic acid, 4 or 8 mg every 3 weeks for 15 consecutive months, or placebo. At 15 and 24 months of follow-up, patients treated with 4 mg zoledronic acid had fewer skeletal-related events (SREs) compared to the placebo group (44% vs. 33%, $P = 0.021$) and fewer pathological fractures (13.1% vs. 22.1%, $P = 0.015$). Furthermore, the time to first SRE was longer in the zoledronic acid group, thus improving QoL.

Patients were initially randomised to 4 or 8 mg of zoledronic acid, but the 8 mg dosage was later modified to 4 mg due to toxicity. The toxicity (e.g., jaw necrosis) of these drugs, especially aminobisphosphonate, must always be kept in mind [859, 860]. Patients should have a dental examination before starting bisphosphonate therapy. The risk of jaw necrosis is increased by a history of trauma, dental surgery or dental infection, as well as long-term intravenous bisphosphonate administration [863].

No survival benefit has been seen in any prospective trial with bisphosphonates.

6.11.8.2.3 RANK ligand inhibitors

Denosumab is a fully human monoclonal antibody directed against RANKL (receptor activator of nuclear factor κ B ligand), a key mediator of osteoclast formation, function, and survival. In M0 CRPC, denosumab has been associated with increased bone-metastasis-free survival compared to placebo (median benefit: 4.2 months, HR: 0.85, $P = 0.028$) [685]. However, this benefit did not translate into a survival difference (43.9 compared to 44.8 months, respectively). The practical impact of this finding remains under discussion. The efficacy and safety of denosumab ($n = 950$) compared with zoledronic acid ($n = 951$) in patients with metastatic CRPC was assessed in a phase III trial. Denosumab was superior to zoledronic acid in delaying or preventing SREs, as shown by time to first on-study SRE (pathological fracture, radiation or surgery to bone, or spinal cord compression) of 20.7 vs. 17.1 months, respectively (HR 0.82; $P = 0.008$). Both urinary NTX and BAP were significantly suppressed in the denosumab arm compared with the zoledronic acid arm ($p < 0.0001$ for both). However, these positive findings were not associated with any survival benefit.

6.11.9 **Conclusion and guidelines for treatment after hormonal therapy (first, second-line modality) in metastatic CRPC**

Conclusion	LE	GR
No definitive strategy regarding treatment choice (which drug/drug family first) can be devised.	4	
Recommendations	LE	GR
In patients with a PSA rise only, two consecutive increases of PSA serum levels above a previous reference level should be documented.	2b	B
Patients should not be started on second-line therapy unless their testosterone serum levels are < 50 ng/dL.	4	A
Patients should not be started on second-line therapy unless their PSA serum levels are > 2 ng/mL to ensure correct interpretation of therapeutic efficacy.	4	B
There is no evidence for treatment of non-metastatic CRPC outside of a clinical trial.	3	A
Men treated with maximal androgen blockade should stop the anti-androgen therapy once PSA progression is documented. <i>Comment: Four to six weeks after discontinuation of flutamide or bicalutamide, an eventual anti-androgen withdrawal effect will be apparent.</i>	2a	A
No clear-cut recommendation can be made for the most effective drug for secondary treatment (i.e. hormone therapy or chemotherapy) as no clear predictive factors exist.	3	A
Salvage hormonal treatment using abiraterone acetate is a valid option.	1b	A
Salvage hormonal treatment using enzalutamide is a valid option.	1b	A

CRPC = castration-resistant prostate cancer; GR = grade of recommendation; LE = level of evidence; PSA = prostate-specific antigen; MAB = maximal androgen blockade.

6.11.10 **Guidelines for cytotoxic treatment and pre/post-docetaxel therapy in mCRPC**

Recommendations	LE	GR
Patients with mCRPC should be counseled, managed and treated by a multidisciplinary team.	3	A
In non-metastatic CRPC, cytotoxic therapy should only be used in a clinical trial setting.	3	B
Prior to treatment, the potential benefits of second-line therapy and expected side effects should be discussed with the patient.		C
In patients with metastatic CRPC who are candidates for salvage cytotoxic therapy, docetaxel at 75 mg/m ² every 3 weeks has shown a significant survival benefit.	1a	A
Docetaxel chemotherapy improves QoL and provides pain relief for men with symptomatic bone metastases due to mCRPC.	1a	A
In patients with relapse following salvage docetaxel chemotherapy, cabazitaxel, abiraterone and enzalutamide are regarded as first-choice options for second-line treatment in mCRPC.	1a	A
In men with mCRPC with symptomatic bone metastases, who are ineligible for or progressing after docetaxel, treatment with Ra 223 (alpharadin) has shown a survival benefit.	1b	A

GR = grade of recommendation; LE = level of evidence; mCRPC = metastatic castration-resistant prostate cancer; PSA = prostate-specific antigen.

6.11.11 **Guidelines for “non-specific” management of mCRPC**

Recommendations	LE	GR
Management of patients with extended symptomatic bone metastases has to be directed at improvement of QoL and mainly pain reduction.	1a	A
Effective medical management with the highest efficacy and a low frequency of side-effects is the major goal of therapy.	1a	A
Bone protective agents may be offered to patients with skeletal metastases (denosumab being superior to zoledronic acid) to prevent osseous complications. However, the benefits must be balanced against the toxicity of these agents, and jaw necrosis in particular must be avoided.	1a	A
Calcium and vitamin D supplementation must be systematically considered when using either denosumab or bisphosphonates.	1b	A
In the management of painful bone metastases, early use of palliative treatments such as radionuclides, external beam radiotherapy and adequate use of analgesics is recommended.	1a	B

In patients with neurological symptoms, spinal surgery or decompressive radiotherapy might be indicated as emergency interventions. High-dose corticosteroids must always be initially considered.	1b	A
--	----	---

GR = grade of recommendation; LE = level of evidence; mCRPC = metastatic castration-resistant prostate cancer.

7. FOLLOW-UP

7.1 Follow-up: After local treatment

7.1.1 Definition

Local treatment is defined as radical prostatectomy (RP) or radiotherapy, either by external beam radiotherapy or low- or high-dose brachytherapy, or any combination of these. Unestablished alternative treatments, such as HIFU and cryosurgery do not have a well-defined, validated PSA cut-off to define biochemical failure, but do follow the outlines below.

7.1.2 Why follow-up?

Recurrence occurs after primary therapy in many patients who have previously received treatment with intent to cure. Reasons for follow-up vary depending on treatment, patient age, comorbidity and the patient's own wishes. Patients who receive curative therapy are followed up to:

- assess immediate- and long-term oncological results, side effects or complications of therapy, functional outcome and to provide psychological support to PCa survivors;
- discuss the possibility of second-line treatment with curative intent; early hormonal therapy or watchful waiting with the patient.

7.1.3 How to follow-up?

The procedures indicated at follow-up visits vary according to clinical situation. The examinations discussed below are routinely used to detect PCa progression or residual disease. PSA level and DRE are the only tests that should be performed routinely. Disease-specific history is mandatory at every follow-up visit and includes psychological aspects, signs of disease progression, and treatment-related complications. Evaluation of treatment-related complications must be individualised and is beyond the scope of these guidelines. The examinations used most often for cancer-related follow-up after curative surgery or radiotherapy are discussed below.

7.1.3.1 Prostate-specific antigen monitoring

Measurement of PSA is a cornerstone in follow-up after local treatment. Expectations differ after RP and radiotherapy, but PSA recurrence often precedes clinical recurrence [864, 865]. A single, elevated, serum PSA level should be confirmed before starting second-line therapy based solely on PSA elevation.

7.1.3.2 Definition of prostate-specific antigen progression

The PSA level for definition of treatment failure differs between RP and radiotherapy. International consensus defines recurrent cancer after RP by two consecutive PSA values ≥ 0.2 ng/mL [866]. However, others have argued for a higher cut-off of 0.4 ng/mL for patients with a high-risk of clinical progression [865].

Ultrasensitive PSA (US PSA) assay remains controversial for routine follow-up after RP. Men with a US PSA nadir < 0.01 ng/mL have a 4% likelihood of early biochemical relapse [867]. Detectable postoperative US PSA does not predict BCR in all cases, although it adds prognostic value. In men with US PSA > 0.05 ng/mL, 66.8% remained free of biochemical disease at 5 years [868]. If survival is improved by early adjuvant treatment after RP (before PSA reaches > 0.2 ng/mL), higher US PSA nadir levels may help to identify suitable candidates.

At the 2006 RTOG-ASTRO Consensus conference, a new definition of radiation failure was proposed to establish better correlation between definition and clinical outcome, namely, an increase of 2 ng/mL above the post-treatment PSA nadir [708]. It applies to patients with or without hormonal therapy.

After HIFU or cryotherapy, there are various definitions for PSA relapse [507]. Most of these are based on a cut-off PSA level of ~ 1 ng/mL, combined with negative post-treatment biopsy. No end-points have been validated against clinical progression or survival; therefore, it is not possible to give a firm recommendation of biochemical failure.

7.1.3.3 Prostate-specific antigen monitoring after radical prostatectomy

Prostate-specific antigen is expected to be undetectable within 6 weeks after successful RP [869]. Persistently elevated PSA in patients treated with RP is thought to be due to residual cancer, either micrometastases or residual pelvic disease.

Rapidly increasing PSA level indicates distant metastases, whereas later, slowly increasing level most likely indicates local recurrence. Time to PSA recurrence and tumour differentiation are important predictive factors distinguishing local and systemic recurrence [870]. Local treatment failure and distant metastases occur with undetectable PSA levels. This is rare and occurs mostly in patients with undifferentiated tumours [871].

Thus, in patients with favourable pathology (< pT3, pN0, Gleason score < 8), PSA measurement and disease-specific history could be a single test in follow-up after RP.

7.1.3.4 PSA monitoring after radiotherapy

PSA level falls slowly after radiotherapy compared with RP. A nadir < 0.5 ng/mL is associated with a favourable outcome after radiotherapy [872], although the optimal value is controversial. The interval before reaching the nadir can be up to 3 years or more. Biochemical failure after radiotherapy is currently defined as PSA > 2 ng/mL above the nadir [708]. After radiotherapy, PSA-DT is correlated with site of recurrence: patients with local recurrence have a DT of 13 months compared to 3 months for those with distant failure [873].

7.1.3.5 Digital rectal examination

Local recurrence after curative treatment is possible without a concomitant rise in PSA level [871]. However, this has only been proven in patients with unfavourable pathology, namely, undifferentiated tumours. PSA measurement and DRE comprise the most useful combination for first-line examination in follow-up after radiotherapy or RP, but PSA measurement may be the only test in cases with favourable pathology (< pT3, pN0, Gleason < 8) [874].

7.1.3.6 Transrectal ultrasonography (TRUS), bone scintigraphy, computed tomography (CT), magnetic resonance imaging (MRI), and ¹¹C-choline positron emission tomography computed tomography (PET/CT)

Imaging techniques have no place in routine follow-up of localised PCa. They are only justified in patients with biochemical failure or in patients with symptoms for whom the findings affect treatment decisions. (See Section 6.19.4 for a more detailed discussion).

7.1.3.6.1 Transrectal ultrasonography/magnetic resonance imaging biopsy

Biopsy of the prostate bed and urethrovesical anastomosis are only indicated if local recurrence affects treatment decisions.

7.1.4 When to follow-up?

Most patients who fail treatment for PCa do so early, even if failure only becomes clinically obvious after years. Patients should be followed-up more closely during the initial post-treatment period when risk of failure is highest. PSA measurement, disease-specific history and DRE are recommended at 3, 6 and 12 months postoperatively, every 6 months thereafter until 3 years, and then annually.

The first clinic visit is mainly to detect treatment-related complications and assist patients in coping with their new situation. Tumour or patient characteristics may allow alterations to this schedule. Patients with poorly differentiated and locally advanced tumours or with positive margins may be followed-up more closely than those with a well-differentiated, intracapsular or specimen-confined tumour. Advanced age or associated comorbidity may make further follow-up in asymptomatic patients superfluous.

7.1.5 Conclusions and guidelines for follow-up after treatment with curative intent

Conclusions	LE
After RP, serum PSA level > 0.2 ng/mL is associated with residual or recurrent disease.	
After radiotherapy, an increase in PSA > 2 ng/mL above the nadir, rather than a specific threshold value, is the most reliable sign of recurrence.	B
Palpable nodules and increasing serum PSA are signs of local recurrence.	B

Recommendations	GR
In asymptomatic patients, disease-specific history and serum PSA measurement supplemented by DRE are recommended for routine follow-up. These should be performed at 3, 6 and 12 months after treatment, then every 6 months until 3 years, and then annually.	B
Imaging to detect local recurrence is only recommended if it affects treatment planning. Biopsy is usually not necessary before second-line therapy, except after EBRT when local salvage treatment is considered.	B
Routine bone scans and other imaging are not recommended in asymptomatic patients if there are no signs of biochemical relapse. In patients with bone pain or other symptoms of progression, re-staging should be considered irrespective of serum PSA level.	B

DRE = digital rectal examination; GR = grade of recommendation; LE = level of evidence; PSA = prostate-specific antigen; RP = radical prostatectomy.

7.2 Follow-up: During hormonal treatment

7.2.1 Introduction

A large proportion of patients treated with hormonal therapy have either metastatic or locally advanced tumours at diagnosis. This will affect the follow-up schedule as biochemical failure is often associated with rapid symptomatic progression.

7.2.2 Purpose of follow-up

The main objectives of follow-up in these patients are to:

- monitor the response to treatment;
- ensure compliance with treatment;
- detect potential complications of endocrine therapy;
- guide the modalities of palliative symptomatic treatment at the time of CRPC.

It is important to be clear about which complementary investigations are helpful at different stages of the disease to avoid unnecessary patient examinations and excessive costs. Based on current knowledge, it is not possible to formulate level 1 evidence guidelines for follow-up procedures following hormonal therapy.

7.2.3 Methods of follow-up

7.2.3.1 Clinical follow-up

Clinical follow-up is mandatory. Neither biology nor imaging modalities can replace face to face clinic visits. Patients should be seen on a regular basis to check for possible troublesome symptoms. Of upmost importance in patients in the M1b stage is to highlight and check for possible early signals of spinal cord compression, urinary tract complications (ureteral obstruction, bladder outlet obstruction, etc) or bone lesions at an increased fracture risk.

7.2.3.1.1 Prostate-specific antigen monitoring

Prostate-specific antigen (PSA) is a good marker for following the course of PCa.

Treatment response may be assessed using the change in serum PSA level as a surrogate endpoint for survival in patients with newly diagnosed metastatic PCa. Patients with a PSA nadir < 0.2 ng/mL after 7 months of treatment have been shown to have the best survival (median 75 months) compared to patients with a value of 0.2-4.0 ng/mL (median 44 months) or > 4.0 ng/mL (median 13 months) [571]. Similar results have been found in locally advanced and metastatic PCa [875, 876], as in salvage ADT for elevated PSA following treatments with curative intent [877].

Patients should be regularly monitored to detect and treat any complications of endocrine treatment as well as disease progression, usually after a median of 12-18 months in patients with stage M1 disease. A rise in PSA level usually precedes the onset of clinical symptoms by several months. However, it must be stressed that the PSA level is insufficient as clinical progression (usually bone pain) with normal PSA levels has been reported.

7.2.3.1.2 Creatinine, haemoglobin and liver function monitoring

Creatinine monitoring is good clinical practice as an increase may be linked to silent bilateral ureteral obstruction or bladder retention. Liver function tests may suggest disease progression and/or toxicity of hormonal treatment (especially non-steroidal antiandrogens), which can lead to interruption of hormonal treatment. A decline in haemoglobin after 3 months of ADT is independently associated with a shorter progression-free and OS [878] and might explain significant fatigue.

Alkaline phosphatase may increase secondary to bone metastases and androgen-induced osteoporosis [879]. Therefore, it may be helpful to determine its bone-specific isoenzymes as none are directly influenced by hormonal therapy.

7.2.3.1.3 Bone scan, ultrasound and chest X-ray

Asymptomatic patients with a stable PSA level should not undergo imaging at regular intervals [207].

In the case of bone symptoms or PSA progression under castration, a bone scan might be helpful, if a treatment modification is considered. The Prostate Cancer Clinical Trials Working Group 2 has clarified the definition of bone scan progression as the appearance of at least two new lesions [880], later confirmed.

Suspicion of disease progression indicates the need for additional imaging modalities, guided by symptoms or subsequent possible treatment decisions. In CRPC, follow-up examinations should be individualised with the aim of maintaining the patient's QoL.

7.2.3.1.4 Testosterone monitoring

Most PCa patients receiving LHRH analogues will achieve serum testosterone values at or below the castration level (< 1 nmol/L). However, approximately 13-38% of patients fail to achieve this therapeutic goal. In addition, up to 24% of men treated with LHRH analogues may experience testosterone surges (testosterone > 50 ng/dL) during long-term treatment, which is described as the 'acute on-chronic effect' or 'breakthrough response'.

The measurement of serum testosterone levels should be considered part of clinical practice for men on LHRH therapy. The timing of testosterone measurements is not clearly defined. A 3 to 6-month testosterone level assessment may be performed to ensure the castration level is being maintained. If it is not being maintained, switching to another LHRH agonist or antagonist or to surgical orchiectomy should be considered. In patients with rising PSA and/or clinical signs of progression, serum testosterone must be evaluated in all cases to confirm a castrate-resistant state.

7.2.3.1.5 Monitoring of metabolic complications

Androgen deprivation therapy is beneficial in patients with PCa, but has a greater range of complications than might be expected. The most severe complications are bone problems, the metabolic syndrome and cardiovascular morbidity (see section 7.5). The patient's GP or family physician should probably be more involved.

All patients should be screened for diabetes by checking fasting glucose and HbA1c (at baseline and then every 3 months), as for blood lipid levels. In selected cases, glucose tolerance testing may be required. Men with impaired glucose tolerance and/or diabetes should be referred for an endocrine consultation. A cardiology consultation should be considered in men with a history of cardiovascular disease and men older than 65 years prior to starting ADT. Monitoring serum levels of vitamin D and calcium is important. If necessary, supplements should be given to ensure a daily intake of at least 1200 mg/day of calcium and 1000 IU of vitamin D. Preventive therapy with bisphosphonates or denosumab using specific doses (which differ from those used in the CRPC stage) could be considered in patients who have an initial T-score of less than -2.5 on DEXA. It is suggested that bone monitoring should be performed every 2 years after castration, provided there are no other risk factors [881], or yearly if there are risk factors [882, 883]. However, prospective trials are needed.

Patients on ADT should be given advice on modifying their lifestyle (e.g. diet, exercise, smoking cessation, etc) and should be treated for any existing conditions, such as diabetes, hyperlipidaemia, and/or hypertension [884, 885]. Furthermore, the risk-to-benefit ratio of ADT must be considered in patients with a higher risk of cardiovascular complications, especially if it is possible to delay starting ADT [676].

7.2.4 **When to follow-up**

After the initiation of hormonal treatment, it is recommended that patients are followed up at 3 and 6 months. These guidelines must be individualised and each patient should be advised to contact his physician in the event of troublesome symptoms.

7.2.4.1 *Stage M0 - M1 patients*

If there is a good treatment response, i.e. PSA response (less than 4 ng/mL), symptomatic improvement, good psychological coping, good treatment compliance, and a serum PSA level of less than 4 ng/mL, follow-up visits are scheduled every 6 months (a 3-month schedule can be considered in M1 patients).

7.2.4.2 *Castration-refractory PCa*

Patients whose disease progresses, or who do not respond according to the criteria mentioned above, warrant an individualised follow-up scheme.

7.2.5 Guidelines for follow-up after hormonal treatment

Recommendations	GR
Patients should be evaluated at 3 and 6 months after the initiation of treatment.	A
As a minimum, tests should include serum PSA measurement, DRE, serum testosterone, and careful evaluation of symptoms in order to assess the treatment response and side effects.	A
In patients undergoing intermittent androgen deprivation, PSA and testosterone should be monitored at fixed intervals during the treatment pause (one or three months).	A
Follow-up should be tailored for the individual patient, according to symptoms, prognostic factors and the treatment given.	A
In patients with stage M0 disease with a good treatment response, follow-up is scheduled every 6 months, and as a minimum should include a disease-specific history, DRE and serum PSA determination.	A
In patients with stage M1 disease with a good treatment response, follow-up is scheduled for every 3 to 6 months. As a minimum, this should include a disease-specific history, DRE and serum PSA determination, and is frequently supplemented with haemoglobin, serum creatinine and alkaline phosphatase measurements. The testosterone level should be checked, especially during the first year.	A
Patients (especially with M1b status) should be advised about the clinical signs that could suggest spinal cord compression.	A
When disease progression occurs, or if the patient does not respond to treatment, follow-up should be individualised.	A
In patients with suspected progression, the testosterone level must be checked. By definition, CRPC is based on the assumption that the patient has a testosterone level of at least < 50 ng/mL (< 1 mL/L).	B
Routine imaging of stable patients is not recommended.	B

CRPC = castrate-resistant prostate cancer; DRE = digital rectal examination; GR = grade of recommendation; PSA = prostate-specific antigen.

9. CONFLICT OF INTEREST

All members of the Prostate Cancer Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: <http://www.uroweb.org/guidelines/>. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

1. INTRODUCTION

1.1 Aims and scope

The European Association of Urology (EAU) Renal Cell Cancer (RCC) Guidelines Panel has compiled these clinical guidelines to provide urologists with evidence-based information and recommendations for the management of RCC.

1.2 Panel composition

The RCC panel is an international group of clinicians consisting of urological surgeons, an oncologist, methodologists, a pathologist and a radiologist, with particular expertise in the field of urological care. For the 2015 guideline update, the panel incorporated a patient advocate to provide a consumer perspective for its guidelines.

All experts involved in the production of this document have submitted potential conflict of interest statements.

The panel is most grateful for the methodological and scientific support provided by the following individuals in specific parts of the guideline document:

- Prof. Dr. O. Hes, pathologist, Plzen (CZ) (Other renal tumours);
- Dr. T. Adewuyi, Aberdeen, UK: (systematic review - Systemic therapy for metastatic disease and providing general assistance for various aspects of the systematic review);
- Dr. H. Bekema, Groningen (NL): (systematic review - Lymph node dissection in localised and locally advanced RCC);
- Dr. F. Stewart, Aberdeen (UK): (systematic review - Tumour thrombus)
- Prof. Dr. A. Graser, radiologist, Munich (DE): (development of a systematic review for the diagnosis and follow-up chapters [in progress]).

1.3 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text versions. Several scientific publications are available as are a number of translations of all versions of the EAU RCC Guidelines [1-3]. All documents are available free access through the EAU website Uroweb: <http://www.uroweb.org/guidelines/online-guidelines/>.

1.4 Publication history and summary of changes

1.4.1 Publication history

The EAU RCC Guidelines were first published in 2000. This 2015 RCC Guidelines document presents a limited update of the 2014 publication.

1.4.2 Summary of changes

All chapters of the 2015 RCC Guidelines have been updated, based on the 2014 update. The consistency of the data work-up will differ between sections. An overview is presented in Table 1.1.

Table 1.1: Description of update and summary of review methodology for the 2015 update

Chapter	Brief description of review methodology
1. Introduction	Not applicable
2. Methods	Not applicable
3. Epidemiology, Aetiology and Pathology	Updated using a structured data assessment. Of particular note is the inclusion of the new Vancouver Classification in the Histology section [4, 5].
4. Staging and grading classification systems	Updated using a traditional narrative review.
5. Diagnostic evaluation	Updated using a systematic review on tumour biopsy. Updated using a structured data assessment [6].
6. Prognosis	Updated using a traditional narrative review, based on a structured literature search.
7. Treatment (Disease management)	Updated using a systematic review mostly based on a literature search from 2000. A new section, 'Management of RCC with venous thrombus' has been added which is based on a systematic review [7]. A new section on recurrent RCC was added.
8. Surveillance following radical or partial nephrectomy or ablative therapies	Updated using a traditional narrative review, based on a structured data search.

Changed recommendations

Recommendations have been rephrased and added to throughout the current document, not resulting in a change in the grade of recommendation (GR). New recommendations have been included in Sections:

3.4 Recommendations for other renal tumours

Recommendations	GR
<p>AMLs, active surveillance is the most appropriate option for most AMLs. Treatment with selective arterial embolisation (SAE) or NSS can be considered in:</p> <ul style="list-style-type: none"> • large tumours (recommended threshold of intervention does not exist, the formerly recommended size of > 4 cm wide is disputed); • females of childbearing age; • patients in whom follow-up or access to emergency care may be inadequate. 	C

7.1.2.2.4 Conclusions and recommendations

Recommendation	GR
PN should be favoured over RN in patients with T1b tumour, whenever feasible.	B

7.2.4.3 Conclusions and recommendations

Conclusions	LE
In patients with locally advanced disease due to clinically enlarged LNs the survival benefit of LND is unclear. In these cases LND can be performed for staging purposes.	3

7.3.3.8 Conclusions and recommendations for systemic therapy in mRCC

Recommendation	LE	GR
Sunitinib can be recommended as first-line therapy for non-clear-cell mRCC.		B

2. METHODS

2.1 Introduction

For sections of the guidelines that have been updated using a systematic review, the review methodology is outlined in detail elsewhere [8]. Briefly, a systematic review of the literature was conducted in accordance with the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines [9]. Important topics and questions were prioritised for the present update. Elements for inclusion and exclusion, including patient population, intervention, comparison, outcomes, study design, and search terms and restrictions were developed using an iterative process involving all members of the panel, to achieve consensus. Individual literature searches were conducted separately for each update question, and in most instances the search was conducted up to the end of November 2013. Two independent reviewers screened abstracts and full texts, carried out data abstraction and assessed risk of bias. The results were presented in tables showing baseline characteristics and summaries of findings. Meta-analyses were performed only for randomised controlled trials (RCTs) which demonstrated consistency and homogeneity of data. When this was not possible, a narrative synthesis of the evidence was provided.

The remaining sections of the guidelines were updated using a traditional narrative review strategy. Structured literature searches using an expert information specialist were designed. Searches of the Cochrane Database of Systematic Reviews, the Cochrane Library of Controlled Clinical Trials, and Medline and Embase on the Dialog-Datastar platform were performed. The controlled terminology of the respective databases was used, and both MesH and Emtree were analysed for relevant entry terms. The search strategies covered the last 3 years (from 2011). An update was carried out before the publication of this document. Other data sources were also consulted, including the Database of Abstracts of Reviews of Effectiveness (DARE), and relevant reference lists from other guidelines producers such as the National Institute for Clinical Excellence (NICE) and the American Urological Association (AUA).

The majority of studies in this guideline update are retrospective analyses that include some larger multicentre studies and well-designed controlled studies. As only a few RCTs are available, most of the data are not based on high levels of evidence. Conversely, in the systemic treatment of metastatic RCC, a number of randomised studies have been performed, resulting in more reliable recommendations based on higher levels of evidence.

In this 2015 EAU Guidelines compilation, all standard information on levels of evidence (LE) and grading of recommendations (GR) has been taken out of the individual guidelines topics for the sake of brevity. This information is included in the introductory section of this print.

2.2 Future goals

In addition to further systematic data work-up, the RCC panel intend to focus on patient-reported outcomes.

The use of clinical quality indicators is an area of interest. A number of key quality indicators for this patient group have been selected:

1. Thorax CT for staging of pulmonary metastasis.
2. Proportion of patients with T1aN0M0 tumours undergoing nephron sparing surgery as first treatment.
3. The proportion of patients treated within 6 weeks after diagnosis.
4. The proportion of patients with metastatic RCC offered treatment with targeting agents.
5. Proportion of patients who undergo minimally invasive or operative treatment as first treatment who die within 30 days.

2.3 Peer review

This document was subjected to double-blind peer review prior to publication.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Renal cell carcinoma (RCC) represents 2-3% of all cancers [10], with the highest incidence in Western countries. Over the last two decades until recently, the incidence of RCC increased by about 2% both worldwide and in Europe, although a continuing decrease has been observed in Denmark and Sweden [11]. In 2012, there were approximately 84,400 new cases of RCC and 34,700 kidney cancer-related deaths in the European Union [12]. In Europe, overall mortality rates for RCC increased up to the early 1990s, and stabilised or declined thereafter [13]. Mortality has decreased since the 1980s in Scandinavian countries and since the early 1990s in France, Germany, Austria, the Netherlands, and Italy. However, in some European countries (Croatia, Estonia, Greece, Ireland, Slovakia), mortality rates still show an upward trend [13].

Different RCC types have specific histopathological and genetic characteristics [14]. There is a 1.5:1 male predominance, with peak incidence between 60 and 70 years. Aetiological factors include smoking, obesity, and hypertension [15-18]. Having a first-degree relative with kidney cancer also increases the risk of RCC [19]. A number of other factors associated with higher or lower RCC risk include specific dietary habits and occupational exposure to specific carcinogens, however, literature results are inconclusive [20, 21]. Moderate alcohol consumption appears to have a protective effect for unknown reasons [22, 23]. Effective prophylaxis includes avoidance of cigarette smoking and obesity.

Due to increased detection of tumours by ultrasound (US) and computed tomography (CT), the number of incidentally diagnosed RCCs has increased. These tumours are usually smaller and of lower stage [24-26].

3.1.1 Conclusion and recommendation

Conclusion	LE
Several verified risk factors have been identified including smoking, obesity and hypertension. These are considered definite risk factors for RCC.	2a

Recommendation	GR
The most important primary prevention for RCC is elimination of cigarette smoking and obesity reduction.	B

3.2 Histological diagnosis

Renal cell carcinomas comprise a broad spectrum of histopathological entities described in 2004 WHO classification [4] and modified by ISUP Vancouver Classification [5]. There are three main RCC types: clear cell (ccRCC), papillary (pRCC - type I and II) and chromophobe (chRCC). RCC type classification has been confirmed by cytogenetic and genetic analyses [27-29] (LE: 2b). Collecting duct carcinoma and other infrequent renal tumours are discussed in Section 3.3.

Histological diagnosis includes, besides RCC type, evaluation of nuclear grade, sarcomatoid features, vascular invasion, tumour necrosis, and invasion of the collecting system and perirenal fat. Fuhrman nuclear grade has been the most widely accepted grading system [30]. At the ISUP conference, a simplified, nuclear grading system, based only on size and shape of nucleoli, has been proposed which will replace the Fuhrman grading system [5].

3.2.1 Clear cell (ccRCC)

Grossly, ccRCC is well circumscribed, capsule is usually absent. The cut surface is golden-yellow, often with haemorrhage and necrosis. The Fuhrman nuclear grading system is generally used [30]. Loss of chromosome 3p and mutation of the VHL (von Hippel-Lindau) gene at chromosome 3p25 are frequently found. ccRCC has a worse prognosis compared with pRCC and chRCC [31, 32] even after stratification for stage and grade [33]. The 5-year CSS rate was 91%, 74%, 67% and 32% for TNM stages I, II, III and IV (patients treated 1987-98) [34]. The indolent variant of ccRCC is multilocular cystic and accounts for approximately 4% of all ccRCC [5].

3.2.2 Papillary (pRCC)

Macroscopically, pRCC is well circumscribed with pseudocapsule, yellow or brown in colour, and a soft structure. Genetically, pRCC shows trisomies of chromosomes 7 and 17 and the loss of chromosome Y. Papillary RCCs are heterogeneous, with three different subtypes; two basic (1 and 2) and a third type,

oncocytic. Compared with ccRCC, pRCC has a significantly higher rate of organ confined tumour (pT1-2N0M0) and higher 5-year CSF [35]. Prognosis of pRCC type 2 is worse than for type 1 [36-38]. Exophytic growth, pseudonecrotic changes and pseudocapsule are typical signs of pRCC type 1. Pseudocapsules and extensive necrotic changes cause a spherical tumour in the extrarenal section. Tumours with massive necroses are fragile and vulnerable to spontaneous rupture or rupture resulting from minimal trauma followed by retroperitoneal bleeding. A well-developed pseudocapsule in pRCCs type 1 probably prevents these tumours from rupturing despite necroses. Necroses cohere with a hypodense central area of tumour on postcontrast CT. This area is surrounded by a vital tumour tissue, seen as a serpiginous contrast-enhancing margin on CT [39]. Some authors consider type 3; oncocytic pRCC, to have no pseudocapsule or massive necrosis, rare extrarenal growth and low malignant potential [38], although this type is not generally accepted [5].

3.2.3 **Chromophobe (chRCC)**

Grossly, chRCC is a pale tan, relatively homogenous and tough, well-demarcated mass without a capsule. Instead of the Fuhrman grading system, a special histopathological grading system by Paner et al. was proposed in 2010 [40, 41]. Loss of chromosomes 2, 10, 13, 17 and 21 are typical genetic changes [42]. The prognosis is relatively good, with high 5-year recurrence-free survival, CSS and 10-year CSS [43].

3.3 **Other renal tumours**

Other renal tumours constitute the remaining 10-15 % of renal cortical tumours. These include a variety of uncommon, sporadic, and familial carcinomas, some only recently described, and a group of unclassified carcinomas. A summary of these tumours are given in Table 3.1, but some clinically relevant tumours and extremely rare entities are mentioned below.

3.3.1 **Carcinoma associated with end-stage renal disease; acquired cystic disease-associated RCC**

Cystic degenerative changes (acquired cystic kidney disease [ACKD]) and a higher incidence of RCC are typical features of ESKD (end-stage kidney disease). RCCs of native end-stage kidneys are found in about 4% of patients. The lifetime risk of developing RCCs is at least 10 times higher than in the general population. Compared with sporadic RCCs, ACKDs generally are multicentric and bilateral, found in younger patients (mostly male), and are less aggressive [44, 45]. The relatively indolent outcome of tumours in ESKD is due to the mode of diagnosis and a specific ACKD related molecular pathway still to be determined [45]. Although the histological spectrum of ACKD tumours is similar to that in sporadic RCC, the predominant form is pRCC. The remaining tumours are mostly ccRCC [44-46]. A specific subtype of RCC occurring in end-stage kidneys only was described as Acquired Cystic Disease-associated RCC (ACD-RCC) [5].

3.3.2 **Papillary adenoma**

These tumours have papillary or tubular architecture of low nuclear grade and are 5 mm in diameter or smaller [4]. They are found incidentally in nephrectomy specimens.

3.3.3 **Hereditary kidney tumours**

Hereditary kidney tumours are found in the following entities: Von Hippel-Lindau syndrome, hereditary pRCC, Birt-Hogg-Dubé syndrome (see Hybrid oncocytoma-chromophobe carcinoma), hereditary leiomyomatosis and renal cell cancer (HLRCC), tuberous sclerosis complex, germline succinate dehydrogenase (SDH) mutation, nonpolyposis colorectal cancer syndrome, hyperparathyroidism-jaw tumour syndrome, PTEN hamartoma syndrome, constitutional chromosome 3 translocation, and familial nonsyndromic ccRCC. RMC can be included because of its association with hereditary haemoglobinopathies [4, 5, 36, 47].

3.3.4 **Angiomyolipoma (AML)**

Angiomyolipoma is a benign mesenchymal tumour, can occur sporadically, and is four times more likely in women. It also occurs in tuberous sclerosis (TS). It accounts for approximately 1% of surgically removed tumours. Ultrasound, CT, and MRI often lead to diagnosis due to the presence of adipose tissue. Biopsy is rarely useful. Pre-operatively, it may be difficult to differentiate between smooth muscle cell tumours and epithelial tumours. AML can be found in TS in LNs, but is not metastases, and has a multicentric genesis. AML can be due to angiotropic-type growth in the renal vein or the IVC. AML with LN involvement and tumorous thrombus is benign. Only epithelioid AML is potentially malignant [4, 48]. AML has a slow and consistent growth rate, and minimal morbidity [49]. The main complications of renal AML are retroperitoneal bleeding or bleeding into the urinary collection system, which can be life-threatening [50]. The bleeding tendency is related to the angiogenic component of the tumour that includes irregular and aneurysmatic blood vessels [50]. The major risk factors for bleeding are tumour size, grade of the angiogenic component, and the presence of TS [50, 51]. Indications for intervention are pain, bleeding, or suspected malignancy.

3.3.4.1 Treatment

Active surveillance (AS) is the most appropriate option for most AMLs [49, 52] (LE: 3). Risk factors for delayed intervention include tumour size ≥ 4 cm and symptoms at diagnosis [52]. Selective arterial embolisation (SAE) seems to be the first-line option used for active treatment after AS was discontinued [52] (LE: 3). SAE is an efficient treatment for AML devascularisation but only volume reduction [53]. And although SAE controls haemorrhage in the acute setting, it has limited value in the longer-term [49, 50]. If surgery is selected, most cases of AML can be managed by conservative NSS, although some patients may require complete nephrectomy [51] (LE: 3). Radiofrequency ablation (RFA) can be option as well [49, 50, 54]. The volume of AML can be reduced by the m-Tor inhibitor everolimus [55] and sirolimus can be combined with deferred surgery [56].

Table 3.1: Other renal cortical tumours, and recommendations for treatment (GR: C)

Entity [4, 5]	Clinical relevant notes	Malignant potential	Treatment of localised tumour/metastatic tumour
Sarcomatoid variants of RCC	Sign of high-grade transformation without being a distinct histological entity	High	Surgery/sunitinib, option of gemcitabine plus doxorubicin [57].
Multilocular ccRCC		Low, no metastasis	Surgery, NSS*
Carcinoma of the collecting ducts of Bellini	Rare, often presenting at an advanced stage (N+ 44% and M1 33% at diagnosis). The hazard ratio in CSS in comparison with ccRCC is 4.49 [32].	High, very aggressive. Median survival 30 months [58].	Surgery/Response to targeted therapies was poor [59].
Renal medullary carcinoma	Very rare. Mainly young black men with sickle cell trait	High, very aggressive, median survival is 5 months [58].	Surgery/different chemotherapy regimes, radiosensitive.
Translocation RCC (TRCC) Xp11.2	Rare, mainly younger patients under 40, more common in females. It constitute with TRCC 6p21 MiT translocation renal cell carcinomas [60].	High	Surgery/VEGF-targeted therapy.
Translocation RCC t(6;11)		Low/intermediate	Surgery, NSS/VEGF-targeted therapy.
Mucinous tubular and spindle cell carcinoma	Tumour is associated with the loop of Henle	Intermediate	Surgery, NSS
Acquired cystic disease-associated RCC		Low	Surgery
Clear cell (tubulo) papillary RCC	It has been reported under the term renal angiomyomatous tumour (RAT) as well.	Low	Surgery, NSS
Tubulocystic RCC	Mainly men, imaging can be Bosniak III or IV.	Low (90% indolent)	Surgery, NSS
Hybrid oncocytic chromophobe tumour	Mixture of cells of chRCC and renal oncocytoma. Three clinicopathological situations: sporadic, in association with renal oncocytosis/oncocytomatosis or in patients with Birt-Hogg-Dubé syndrome.	Low or benign	Surgery, NSS
Metanephric tumours	Divided into metanephric adenoma, adenofibroma, and metanephric stromal tumours.	Benign	Surgery, NSS

Cystic nephroma/ Mixed Epithelial and Stromal Tumour	Term renal epithelial and stromal tumours (REST) is used as well. Imaging – Bosniak type III or II/IV.	Low/benign	Surgery, NSS
Oncocytoma	3-7% of all renal tumours. Imaging characteristics alone are unreliable when differentiating between oncocytoma and RCC. Histopathological diagnosis remains the reference standard [61, 62].	Benign	Observation (when histologically confirmed) [63, 64]/NSS.
Hereditary kidney tumours	Details see above	High	Surgery, NSS
Angiomyolipoma	Details see above	Benign	Consider treatment only in very well selected patients.
Carcinoma associated with neuroblastoma	Long-term survivors of childhood neuroblastoma have a 329-fold increased risk of renal carcinoma.	Variable	Surgery, NSS
Thyroid-like follicular carcinoma of the kidney (TLFC)	Succinate Dehydrogenase B Mutation-associated RCC, ALK Translocation RCC (ALK - anaplastic lymphoma kinase).	Low	Surgery, NSS
Unclassified RCC	RCC that cannot be assigned to any other category of RCC- type carcinoma [4].	Variable	Surgery, NSS

*NSS = *nephron-sparing surgery*; CSS = *cancer specific survival*.

3.3.4.2 Summary

A variety of renal tumours exist, and about 15% are benign. All kidney lesions require examination for malignant behaviour.

3.4 Conclusions and recommendations

Conclusions	LE
Except for AML, most other renal tumours cannot be differentiated from RCC by radiology and should be treated in the same way as RCC.	3
In biopsy-proven oncocytomas, watchful waiting is an option.	3
In advanced uncommon renal tumours, a standardised oncological treatment approach does not exist.	3

Recommendations	GR
Bosniak cysts \geq type III should be regarded as RCC and treated accordingly.	C
AMLs, active surveillance is the most appropriate option for most AMLs. Treatment with selective arterial embolisation (SAE) or NSS can be considered in: <ul style="list-style-type: none"> large tumours (recommended threshold of intervention does not exist, the formerly recommended size of > 4 cm is disputed); females of childbearing age; patients in whom follow-up or access to emergency care may be inadequate. 	C

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Staging

The TNM classification system is recommended for clinical and scientific use [65], but requires continuous improvements [66]. The latest version was published in 2009 with supplement 2012 (Table 4.1), and its prognostic value was confirmed in single and multi-institution studies [67, 68]. Tumour size, venous invasion, renal capsular invasion, adrenal involvement, and lymph node (LN) and distant metastasis are included in the TNM classification system (Table 4.1). However, some uncertainties remain:

- The sub-classification of T1 tumours using a cut-off of 4 cm might not be optimal in NSS for localised cancer.
- The value of size stratification of T2 tumours has been questioned [69].
- Since the 2002 version, tumours with renal sinus fat invasion have been classified as pT3a. However, renal sinus fat invasion might carry a worse prognosis than perinephric fat invasion but is included in the same pT3a stage group [70-72] (LE: 3).
- Sub T-stages (pT2b, pT3a, pT3c and pT4) may overlap [68].
- For adequate M staging, accurate preoperative imaging (chest and abdominal CT) should be performed [73, 74] (LE: 4).

Table 4.1: 2009 TNM classification system [65] and TNM supplement 2012 [75]

T - Primary tumour			
TX	Primary tumour cannot be assessed		
T0	No evidence of primary tumour		
T1	Tumour ≤ 7 cm in greatest dimension, limited to the kidney		
	T1a	Tumour ≤ 4 cm in greatest dimension, limited to the kidney	
	T1b	Tumour > 4 cm but ≤ 7 cm in greatest dimension	
T2	Tumour > 7 cm in greatest dimension, limited to the kidney		
	T2a	Tumour > 7 cm but ≤ 10 cm in greatest dimension	
	T2b	Tumours > 10 cm limited to the kidney	
T3	Tumour extends into major veins or perinephric tissues but not into the ipsilateral adrenal gland or beyond Gerota's fascia		
	T3a	Tumour grossly extends into the renal vein or its segmental (muscle-containing) branches, or invades perirenal and/or renal sinus fat (peripelvic), but not beyond Gerota's fascia	
	T3b	Tumour grossly extends into the vena cava (VC) below the diaphragm	
	T3c	Tumour grossly extends into vena cava above the diaphragm or invades the wall of the VC	
T4	Tumour invades beyond Gerota's fascia (including contiguous extension into the ipsilateral adrenal gland)		
N - Regional LNs			
NX	Regional LNs cannot be assessed		
N0	No regional LN metastasis		
N1	Regional LN metastasis		
M - Distant metastasis			
M0	No distant metastasis		
M1	Distant metastasis		
TNM stage grouping			
Stage I	T1	N0	M0
Stage II	T2	N0	M0
Stage III	T3	N0	M0
	T1, T2, T3	N1	M0
Stage IV	T4	Any N	M0
	Any T	Any N	M1

A help desk for specific questions about TNM classification is available at <http://www.uicc.org/tnm>.

4.2 Anatomic classification systems

Objective anatomic classification systems, such as the Preoperative Aspects and Dimensions Used for an Anatomical (PADUA) classification system, the R.E.N.A.L. nephrometry score and the C-index have been

proposed, to standardise the description of renal tumours [76-78]. These systems include assessment of tumour size, exophytic/endophytic properties, nearness to the collecting system and renal sinus, and anterior/posterior location.

The use of such a system is helpful as it allows objective prediction of potential morbidity of NSS and tumour ablation techniques. These tools provide information for treatment planning, patient counselling, and comparison of PN and tumour ablation series. However, when selecting the best treatment option, anatomic scores must always be considered together with patient features and surgeon experience.

5. DIAGNOSTIC EVALUATION

5.1 Symptoms

Many renal masses remain asymptomatic until the late disease stages. More than 50% of RCCs are detected incidentally by non-invasive imaging used to investigate various nonspecific symptoms and other abdominal diseases [68, 79] (LE: 3). The classic triad of flank pain, gross haematuria, and palpable abdominal mass is rare (6-10%) and correlates with aggressive histology and advanced disease [80, 81] (LE: 3).

Paraneoplastic syndromes are found in approximately 30% of patients with symptomatic RCCs (LE: 4). Some symptomatic patients present with symptoms caused by metastatic disease, such as bone pain or persistent cough [82] (LE: 3).

5.1.1 Physical examination

Physical examination has a limited role in RCC diagnosis. However, the following findings should prompt radiological examinations:

- Palpable abdominal mass;
- Palpable cervical lymphadenopathy;
- Non-reducing varicocele and bilateral lower extremity oedema, which suggests venous involvement.

5.1.2 Laboratory findings

Commonly assessed laboratory parameters are serum creatinine, glomerular filtration rate (GFR), complete cell blood count, erythrocyte sedimentation rate, liver function study, alkaline phosphatase, lactate dehydrogenase (LDH), serum corrected calcium [83, 84], coagulation study, and urinalysis (LE: 4).

For central renal masses abutting or invading the collecting system, urinary cytology and possibly endoscopic assessment should be considered in order to exclude urothelial cancer (LE: 4).

Split renal function should be estimated using renal scintigraphy in the following situations [85, 86] (LE: 2b):

- when renal function is compromised, as indicated by increased serum creatinine or significantly decreased GFR;
- when renal function is clinically important - e.g., in patients with a solitary kidney or multiple or bilateral tumours.

Renal scintigraphy is an additional diagnostic option in patients at risk of future renal impairment due to comorbid disorders.

5.2 Imaging investigations

Most renal tumours are diagnosed by abdominal US or CT performed for other medical reasons [79] (LE: 3). Renal masses are classified as solid or cystic based on imaging findings.

5.2.1 Presence of enhancement

With solid renal masses, the most important criterion for differentiating malignant lesions is the presence of enhancement [87] (LE: 3). Traditionally, US, CT, or magnetic resonance imaging (MRI) are used for detecting and characterising renal masses. Most renal masses are diagnosed accurately by imaging alone. Contrast-enhanced US can be helpful in specific cases [88-90] (LE: 3).

5.2.2 CT or MRI

CT or MRI are used to characterise renal masses. Imaging must be performed before and after administration of intravenous contrast material to demonstrate enhancement. In CT imaging, enhancement in renal masses is determined by comparing Hounsfield units (HUs) before and after contrast administration. A change of 15 or more HUs demonstrates enhancement [91] (LE: 3). To maximise differential diagnosis and detection, the

evaluation should include images from the nephrographic phase for best depiction of renal masses, which do not enhance to the same degree as the renal parenchyma.

CT or MRI allow accurate diagnosis of RCC, but cannot reliably distinguish oncocytoma and fat-free angiomyolipoma from malignant renal neoplasms [61, 92-94] (LE: 3). Abdominal CT provides information on:

- Function and morphology of the contralateral kidney [95] (LE: 3);
- Primary tumour extension;
- Venous involvement;
- Enlargement of locoregional lymph nodes;
- Condition of the adrenal glands and other solid organs (LE: 3).

Abdominal contrast-enhanced biphasic CT angiography is useful in selected cases for detailed information on renal vascular supply [96, 97].

If the results of CT are indeterminate, MRI may provide additional information on:

- enhancement in renal masses [98];
- locally advanced malignancy [99-101];
- venous involvement if the extent of an inferior vena cava (IVC) tumour thrombus is poorly defined on CT [99-102] (LE: 3). Doppler US is less accurate for identifying the extent of a venous tumour thrombus [101] (LE: 3).

MRI is indicated in patients who are allergic to intravenous CT contrast medium and in pregnancy without renal failure [100, 103] (LE: 3). Advanced MRI techniques such as diffusion-weighted and perfusion-weighted imaging are being explored for renal mass assessment [104].

In patients with hereditary RCC who are worried about the radiation exposure of frequent CT scans, MRI may be offered as alternative.

5.2.3 **Other investigations**

Renal arteriography and inferior venacavography have a limited role in the work-up of selected RCC patients (LE: 3). In patients with any sign of impaired renal function, an isotope renogram and total renal function evaluation should be considered to optimise treatment decision-making [85, 86] (LE: 2a).

The value of positron-emission tomography (PET) in the diagnosis and follow-up of RCC remains to be determined, and PET is not currently recommended [105] (LE: 3).

5.2.4 **Radiographic investigations for metastatic RCC**

Chest CT is accurate for chest staging [73, 74, 106-108] (LE: 3). However, routine chest radiography must be performed for metastases, but is less accurate than chest CT (LE: 3). There is a consensus that most bone and brain metastases are symptomatic at diagnosis, thus routine bone or brain imaging is not generally indicated [106, 109, 110] (LE: 3). However, bone scan, brain CT, or MRI may be used in the presence of specific clinical or laboratory signs and symptoms [110-112] (LE: 3).

5.2.5 **Bosniak classification of renal cystic masses**

This classification system classifies renal cysts into five categories, based on CT imaging appearance, to predict malignancy risk [113, 114] (LE: 3). This system also advocates treatment for each category (Table 5.1).

Table 5.1: Bosniak classification of renal cysts [113]

Bosniak category	Features	Work-up
I	Simple benign cyst with a hairline-thin wall without septa, calcification, or solid components. Same density as water and does not enhance with contrast medium.	Benign
II	Benign cyst that may contain a few hairline-thin septa. Fine calcification may be present in the wall or septa. Uniformly high-attenuation lesions < 3 cm in size, with sharp margins without enhancement.	Benign
IIF	These may contain more hairline-thin septa. Minimal enhancement of a hairline-thin septum or wall. Minimal thickening of the septa or wall. The cyst may contain calcification, which may be nodular and thick, with no contrast enhancement. No enhancing soft-tissue elements. This category also includes totally intrarenal, non-enhancing, high attenuation renal lesions ≥ 3 cm. Generally well-margined.	Follow-up. Some are malignant.

III	These are indeterminate cystic masses with thickened irregular walls or septa with enhancement.	Surgery or active surveillance – see Chapter 7. Over 50% are malignant
IV	Clearly malignant containing enhancing soft-tissue components.	Surgery. Most are malignant.

5.3 Renal tumour biopsy

Percutaneous renal tumour biopsy can reveal histology of radiologically indeterminate renal masses and should be considered to select patients with small masses for active surveillance, to obtain histology before ablative treatments and to select the most suitable form of medical and surgical treatment strategy in the setting of metastatic disease [115-124] (LE: 3). Due to the high diagnostic accuracy of abdominal imaging, renal tumour biopsy is not necessary in patients with a contrast-enhancing renal mass for whom surgery is planned (LE: 4).

Percutaneous sampling can be performed under local anaesthesia with needle core biopsy and/ or fine needle aspiration (FNA). Biopsies can be performed with US or CT guidance, with a similar diagnostic yield [120, 123] (LE: 2b). Eighteen-gauge needles are ideal for core biopsies, as they result in low morbidity and provide sufficient tissue for diagnosis [115-123, 125] (LE: 2b). A coaxial technique allowing multiple biopsies through a coaxial cannula should always be used to avoid potential tumour seeding [115, 116-123] (LE: 3).

Core biopsies should be preferred for the characterization of solid renal masses (LE: 2b). A systematic review and meta-analysis of the diagnostic performance and complications of RTB was recently performed by the panel. Fifty-seven articles including a total of 5228 patients were included in the analysis. Needle core biopsies were found to have better accuracy for the diagnosis of malignancy compared with FNA [6]. Other studies showed that solid pattern and larger tumour size are predictors of a diagnostic core biopsy [120, 123] (LE: 2b).

In experienced centres, core biopsies have a high diagnostic yield, specificity, and sensitivity for the diagnosis of malignancy [6] (LE: 2b). However, 0-22.6% of core biopsies are non-diagnostic [115-123, 126-142] (LE: 2b). If a biopsy is non-diagnostic, and radiologic findings are suspicious for malignancy, a further biopsy or surgical exploration should be considered (LE: 4). Assessment of tumour grade on core biopsies is challenging. The accuracy of nuclear grading of biopsies is poor (62.5% on average), but can be improved (87% on average) using a simplified two-tier system (high-grade vs. low grade) [6] (LE: 2b).

The ideal number and location of core biopsies are undefined. However, at least two good quality cores should be obtained, and necrotic areas should be avoided to maximise diagnostic yield [115, 117, 120, 121, 123] (LE: 4). Peripheral biopsies are preferable for larger tumours, to avoid areas of central necrosis [143] (LE: 2b).

Core biopsies have a low diagnostic yield for cystic masses and are not recommended alone, unless areas with a solid pattern are present (Bosniak IV cysts) [120, 123] (LE: 2b). Combined FNA and core biopsies can provide complementary results, especially for complex cystic lesions [122, 127-129, 140, 144, 145] (LE: 3).

Overall, percutaneous biopsies have low morbidity [6]. Spontaneously resolving subcapsular/ perinephric haematoma are frequent complications, while clinically significant bleeding is unusual (0.0-1.4%) and generally self-limiting.

6. PROGNOSTIC FACTORS

Prognostic factors can be classified into: anatomical, histological, clinical, and molecular.

6.1 Anatomical factors

Tumour size, venous invasion, renal capsular invasion, adrenal involvement, and lymph node (LN) and distant metastasis are included in the TNM classification system [65] (Table 4.1).

6.2 Histological factors

Histological factors include Fuhrman grade, RCC subtype, sarcomatoid features, microvascular invasion, tumour necrosis, and invasion of the collecting system. Fuhrman nuclear grade is the most widely accepted grading system [30]. Although affected by intra- and inter-observer discrepancies, it is an independent prognostic factor [146]. A simplified two- or three-strata system may be as accurate for prognostication as the classical four-tiered grading scheme [147, 148] (LE: 3). In univariate analysis, patients with chRCC vs. pRCC vs. ccRCC had a better prognosis [149, 150]. However, prognostic information provided by the RCC type is lost

when stratified to tumour stage [31, 150] (LE: 3).

Differences in tumour stage, grade and cancer specific survival (CSS) between the RCC types are illustrated in Table 6.1.

Table 6.1: Basic characteristics of three main types of RCC [31, 32, 151]

Type	Percentage of RCC (~)	Advanced disease at diagnosis (T3-4, N+, M+)	Fuhrman Grade 3 or 4 [30]	CSS (HR)
ccRCC	80-90%	28%	28.5%	referent
pRCC	6-15%	17.6%	28.8%	0.64 - 0.85
chRCC	2-5%	16.9%	32.7%*	0.24 - 0.56

CSS = cancer-specific survival; HR = hazard ratio.

*The Fuhrman grading system is validated for ccRCC, but is unreliable for chRCC. Data based on the Paner et al. grading system are not available yet [30, 40, 41].

In all RCC types, prognosis worsens with stage and histopathological grade (Tables 6.2 and 6.3).

The 5-year overall survival (OS) for all types of RCC is 49%, which has improved since 2006 probably due to an increase in incidentally detected RCCs and the introduction of TKI inhibitors [152]. Sarcomatoid changes can be found in all RCC types and are equivalent of high grade and very aggressive tumours.

Table 6.2: CSS by stage and histopathological grade in RCCs - hazard ratio (95% CI) (Keegan et al, 2012 [32]).

T1N0M0	Referent
T2N0M0	2.71 (2.17-3.39)
T3N0M0	5.20 (4.36-6.21)
T4N0M0	16.88 (12.40-22.98)
N+M0	16.33 (12.89-20.73)
M+	33.23 (28.18-39.18)
Grade 1	Referent
Grade 2	1.16 (0.94-1.42)
Grade 3	1.97 (1.60-2.43)
Grade 4	2.82 (2.08-3.31)

CI = confidential interval.

Long-term survival in RCC patients treated by radical (RN) or partial nephrectomy (PN) between 1970 and 2003; for unilateral, sporadic ccRCC, pRCC or chRCC in a cohort study [151] (Table 6.3).

Table 6.3: CSS of surgically treated patients by RCC type (estimated survival rate in percentage [95% CI])

Survival time	5 years (%)	10 years (%)	15 years (%)	20 years (%)
ccRCC	71 (69-73)	62 (60-64)	56 (53-58)	52 (49-55)
pRCC	91 (88-94)	86 (82-89)	85 (81-89)	83 (78-88)
chRCC	88 (83-94)	86 (80-92)	84 (77-91)	81 (72-90)

Two subgroups of pRCC with different outcomes have been identified [153]: Type 1 are low-grade tumours with a chromophilic cytoplasm and a favourable prognosis. Type 2 are mostly high-grade tumours with an eosinophilic cytoplasm and a propensity for metastases (LE: 3).

RCC with Xp 11.2 translocation has a poor prognosis [154]. Its incidence is low, but should be systematically addressed in young patients.

RCC type classification has been confirmed by cytogenetic and genetic analyses [27-29] (LE: 2b).

6.3 Clinical factors

These include performance status, localised symptoms, cachexia, anaemia, and platelet count [82, 155-157] (LE: 3).

6.4 Molecular factors

Numerous molecular markers such as carbonic anhydrase IX (CAIX), vascular endothelial growth factor (VEGF), hypoxia-inducible factor (HIF), Ki67 (proliferation), p53, PTEN (phosphatase and tensin homolog) (cell cycle), E-cadherin, C-reactive protein (CRP), osteopontin [158] and CD44 (cell adhesion) [159, 160] have been investigated (LE: 3). None of these markers have improved the predictive accuracy of current prognostic systems and their use is not recommended in routine practice. Although gene expression profiling seems promising, it has not identified new relevant prognostic factors [161].

6.5 Prognostic systems and nomograms

Postoperative prognostic systems and nomograms combining independent prognostic factors have been developed and externally validated [162-168]. These may be more accurate than TNM stage or Fuhrman grade alone for predicting survival (LE: 3). An advantage of nomograms is their ability to measure predictive accuracy (PA), allowing all new predictive parameters to be objectively evaluated. Before being adopted, new prognostic variables or systems should demonstrate that its PA is superior to conventional postoperative histo-prognostic schemes [169]. Recently, new preoperative nomograms with excellent PAs have been designed [170, 171].

Table 6.4 summarises the current most relevant prognostic systems.

6.6 Conclusion and recommendations

Conclusion	LE
In RCC patients, TNM stage, Fuhrman nuclear grade, and RCC subtype (WHO, 2004; [21]), provide important prognostic information.	2

Recommendations	GR
Use of the current TNM classification system.	B
Grading systems and classification of RCC subtype.	B
Prognostic systems in the metastatic setting.	B
In localised disease, the use of integrated prognostic systems or nomograms is not routinely recommended, although they can provide a rationale for enrolling patients into clinical trials.	C
Molecular prognostic markers are not recommended for routine clinical use.	C

Table 6.4: Anatomical, histological, and clinical variables in the commonly used prognostic models for localised and metastatic RCC

Prognostic Models		Variables													
		TNM Stage	ECOG PS	Karnofsky PS	RCC related symptoms	Fuhrman grade	Tumour necrosis	Tumour size	Delay between diagnosis and treatment	LDH	Corrected calcium	Hemoglobin	Neutrophil count	Platelet count	
Localised RCC	UISS	X	X			X									
	SSIGN	X				X	X								
	Post operative Karakiewicz's nomogram	X			X	X	X								
Metastatic RCC	MSKCC prognostic system			X					X	X	X				
	Heng's model			X					X		X	X	X	X	

ECOG PS = Eastern Cooperative Oncology Group performance status; LDH = lactate dehydrogenase; MSKCC = Memorial Sloan Kettering Cancer Center;

PS = performance status; SSIGN = Stage Size Grade Necrosis; UISS = University of California Los Angeles integrated staging system.

7. DISEASE MANAGEMENT

7.1 Treatment of localised RCC

7.1.1 Introduction

A systematic review underpins the findings of Sections 7.1.2 through 7.2.4.2. This review included all relevant published literature comparing surgical management of localised RCC (T1-2N0M0) [172, 173]. Randomised or quasi-randomised controlled trials (RCTs) were included. However, due to the very limited number of RCTs, nonrandomised studies (NRS), prospective observational studies with controls, retrospective matched-pair studies, and comparative studies from the databases of well-defined registries were also included. For this Guidelines version, an updated search was performed up to May 31st, 2013 [174].

7.1.2 Surgical treatment

7.1.2.1 Nephron-sparing surgery versus radical nephrectomy

Based on current available oncological and QoL outcomes, localised renal cancers are better managed by NSS (partial nephrectomy, PN) rather than radical nephrectomy (RN), irrespective of the surgical approach.

The estimated CSS rates at 5 years were comparable using these surgical techniques [175-179]. This was recently confirmed in a study of solitary T1-2 N0M0 renal tumours ≤ 5 cm with normal contralateral kidney function and WHO PS 0-2. At 9.3 years survival follow-up, 198 patients were alive after RN and 173 after PN. The CSS was 98.5 vs 97%, respectively. Local recurrence occurred in one and 6 patients in the RN and PN group, respectively [180].

A number of studies compared PN vs. RN (open or laparoscopic) for renal carcinoma (≤ 4 cm) [180-184]. RN was associated with increased mortality from any cause after adjusting for patient characteristics. In a prematurely closed randomised study of RCC ≤ 5 cm, comparing PN and RN, there was no difference in OS in the targeted population [179]. In studies analysing RCCs of 4-7 cm, no differences in CSS was observed between PN and RN [183, 185-192]. When laparoscopic PN was compared with laparoscopic RN in RCCs > 4 cm, there was no difference in OS, CSS and recurrence-free survival (RFS) rates [193]. Furthermore, a retrospective matched-pair analysis in elderly patients [194] reported a CSS of 98% for PN vs. 95% for RN.

Other studies have compared various aspects of QoL and safety in open PN and RN [175-178, 190, 192, 195-197].

There was no difference in the length of hospital stay [176, 177, 196], blood transfusions [176, 196, 197], or mean blood loss [176, 196]. Complication rates were inconsistently reported and one intervention was not favoured over another [198]. One study found that mean operative time was longer for open PN [198], but other research found no difference [199]. Three studies consistently reported worse renal function after RN compared to PN [175, 178]. More patients had impaired post-operative renal function after RN after adjustment for diabetes, hypertension and age [178].

One database review compared open PN with laparoscopic RN in RCCs 4-7 cm. A significantly lower mean increase in post-operative creatinine levels was found [186]. Another study comparing laparoscopic PN vs. laparoscopic RN found that estimated GFR (eGFR) decreased less in the PN group, while the RN group had significantly more patients with a two-stage increase in CKD [193]. Another database review [200] compared safety and efficacy of laparoscopic PN in RCCs > 2 cm (2-4 cm versus > 4 cm). The laparoscopic PN group had a greater post-operative decrease in eGFR compared to the patients with smaller RCCs.

Two studies reported QoL post-surgery for RCC. Patients who underwent PN reported better scores, in many aspects of QoL [195]. Those who underwent RN reported more fear associated with living with only one kidney. Regardless of the intervention, patients with RCCs < 4 cm and a normal contralateral kidney showed the highest QoL scores after treatment, which matched their pre-diagnosis scores. Those with more complications had lower QoL scores [176].

No prospective comparative studies reporting oncological outcomes for minimally invasive ablative procedures compared with RN were identified. One trial reported on RFA vs. RN or PN for T1a RCC, resulting in CSS of 100% for all three treatments [201].

Patient and tumour characteristics permitting, the current oncological outcomes evidence base suggests that localised RCCs are best managed by PN than RN, irrespective of the surgical approach. Where open surgery is necessary, the oncological outcomes following open PN are at least as good as open RN and should be the preferred option when feasible.

PN is unsuitable in some patients with localised RCC due to:

- locally advanced tumour growth;
- partial resection is not feasible due to unfavourable tumour location;
- significant deterioration in patient health.

In these situations, the curative therapy is RN, including removal of the tumour-bearing kidney. Complete resection of the primary tumour by open or laparoscopic surgery offers a reasonable chance of cure.

7.1.2.2 Associated procedures

7.1.2.2.1 Adrenalectomy

One prospective NRS compared the outcomes of RN or PN with, or without, ipsilateral adrenalectomy [202]. Multivariate analysis showed that upper pole location was not predictive of adrenal involvement, but tumour size was. No difference in OS at 5 or 10 years was seen, with, or without, adrenalectomy. Adrenalectomy was justified using criteria based on radiographic and intra-operative findings. Only 48 of 2,065 patients underwent concurrent ipsilateral adrenalectomy of which 42 were for benign lesions.

7.1.2.2.2 Lymph node dissection for clinically negative lymph nodes (cN0)

Lymph node dissection (LND) in RCC is controversial [203]. Clinical assessment of LNs status is based on enlargement of LNs on CT/MRI and intraoperative assessment by direct palpation. Less than 20% of clinically positive (cN+) LNs are confirmed to be metastatic at pathology (pN+) [204]. CT/MRI do not allow detection of small metastases in normal sized LNs [205] and extended LND (e-LND) with histopathological examination is the only way to assess LNs status. For clinically positive LNs (cN+) see Section 7.2. on locally advanced RCC. In patients with clinically negative LNs (cN0) six clinical trials have been reported [203], one RCT [204] and five comparative studies [206-210].

Retrospective series support the hypothesis that LND may be beneficial in high-risk patients [205, 211]. However, in the EORTC study only 4% of cN0 patients had positive LNs at final pathology, suggesting that LND represents overtreatment in the majority [204].

Clinical trials of lower quality suggest that e-LND should involve the LNs surrounding the ipsilateral great vessel and the interaortocaval region from the crus of the diaphragm to the common iliac artery. Involvement of interaortocaval LNs without regional hilar involvement is reported in up to 35-45% of cases [205, 206, 212]. At least 15 LNs should be removed [213, 214]. Sentinel LND is an investigational technique [215, 216]. Better survival outcomes are seen in patients with a low number of positive LNs (< 4) and no extranodal extension [217, 218]. A preoperative nomogram to predict pN+ LNs status has been proposed [219].

7.1.2.2.3 Embolisation

Before routine nephrectomy, tumour embolisation has no benefit [220, 221]. In patients unfit for surgery, or with non-resectable disease, embolisation can control symptoms, including gross haematuria or flank pain [222-224]. These indications will be repeated in Sections 7.2 and 7.3 with cross reference to the conclusions and recommendations below.

7.1.2.2.4 Conclusions and recommendations

Conclusions	LE
PN achieves similar oncological outcomes to RN for clinically localised tumours (cT1).	1b
Ipsilateral adrenalectomy during RN or PN has no survival advantage.	3
In patients with localised disease without evidence of LN metastases, there is no survival advantage of LND in conjunction with RN.	1b
In patients unfit for surgery with massive haematuria or flank pain, embolisation can be a beneficial palliative approach.	3

Recommendations	GR
Surgery is recommended to achieve cure in localised RCC.	B
PN is recommended in patients with T1a tumours.	A
PN should be favoured over RN in patients with T1b tumour, whenever feasible.	B
Ipsilateral adrenalectomy is not recommended when there is no clinical evidence of invasion of the adrenal gland.	B
LND is not recommended in localised tumour without clinical evidence of LN invasion.	A

7.1.3 Radical and partial nephrectomy techniques

7.1.3.1 Radical nephrectomy techniques

No RCTs have assessed oncological outcomes of laparoscopic vs. open RN. A cohort study [225] and retrospective database reviews are available, mostly of low methodological quality [176, 226, 227]. Similar

oncological outcomes for laparoscopic vs. open RN were found. Data from one RCT [228] and two NRSs [176, 225] showed a significantly shorter hospital stay and lower analgesic requirement for the laparoscopic RN group compared with the open group. Convalescence time was also significantly shorter [225]. No difference in the number of patients receiving blood transfusions was observed, but peri-operative blood loss was significantly less in the laparoscopic arm in all three studies [176, 225, 228]. Surgical complications were marked by low event rates and very wide confidence intervals. There was no difference in complications, but operation time was significantly shorter in the open nephrectomy arm. Post-operative QoL scores were similar [176].

The best approach for RN was the retroperitoneal or transperitoneal with similar oncological outcomes in the two RTCs [229, 230] and one quasi-randomised study [231]. QoL variables were similar in the two approaches.

Hand-assisted vs. standard laparoscopic RN was compared in one RCT [231] and one database review [198]. Estimated 5-year OS, CSS, and RFS rates were comparable. Duration of surgery was significantly shorter in the hand-assisted approach, while length of hospital stay and time to non-strenuous activities were shorter for the standard laparoscopic RN [198, 231]. However, the sample size was small.

Robot-assisted laparoscopic RN vs. laparoscopic RN was compared in one small study [232]. There were no local recurrences, port-site or distant metastases, but the sample size was small and follow-up was short. Similar results were seen in observational cohort studies comparing 'portless' and 3-port laparoscopic RN [233, 234]. Peri-operative outcomes were similar.

7.1.3.2 *Partial nephrectomy techniques*

Studies comparing laparoscopic PN and open PN found no difference in PFS [235-238] and OS [237, 238] in centres with laparoscopic expertise. The mean estimated blood loss is lower with the laparoscopic approach [235, 237, 239], while post-operative mortality, DVT, and pulmonary embolism events are similar [235, 237]. Operative time is generally longer with the laparoscopic approach [236-238] and warm ischaemia time is shorter with the open approach [235, 237, 239, 240]. In a matched-pair comparison, GFR decline was greater in the laparoscopic PN group in the immediate post-operative period [238], but not after a follow-up of 3.6 years. In another comparative study, the surgical approach was not an independent predictor for post-operative CKD [240]. Retroperitoneal and transperitoneal laparoscopic PN have similar peri-operative outcomes [241]. Simple tumour enucleation has similar PFS and CSS rates compared to standard PN and RN in a large study [242, 243].

The feasibility of off-clamp laparoscopic PN and laparoendoscopic single-site PN has been shown in selected patients, but larger studies are needed to confirm their safety and clinical role [244, 245].

No studies have compared the oncological outcomes of robot-assisted vs. laparoscopic PN. A comparison of surgical outcomes after robotic or pure laparoscopic PN in moderate-to-complex renal tumours showed a significantly lower estimated blood loss and a shorter warm ischaemia time in the robotic group [246]. Two recent meta-analyses of relatively small series showed comparable peri-operative outcomes and a shorter warm ischaemia time for robot-assisted PN [247, 248].

7.1.3.3 *Conclusions and recommendations*

Conclusions	LE
Laparoscopic RN has lower morbidity than open surgery.	1b
Oncological outcomes for T1-T2a tumours are equivalent between laparoscopic and open RN.	2a
PN can be performed, either with an open, pure laparoscopic or robot-assisted approach, based on surgeon's expertise and skills.	2b

Recommendations	GR
Laparoscopic RN is recommended for patients with T2 tumours and localised masses not treatable by PN.	B
RN should not be performed in patients with T1 tumours for whom PN is indicated.	B

7.1.4 *Therapeutic approaches as alternatives to surgery*

7.1.4.1 *Surgical versus non-surgical treatment*

Population-based studies compared the oncological outcomes of surgery (RN or PN) and non-surgical management for tumours < 4 cm. The analyses showed a significantly lower cancer-specific mortality for patients treated with surgery [249, 250]. However, the patients assigned to the surveillance arm were older and

likely to be more frail and less suitable candidates for surgery to be addressed. Other cause mortality rates in the non-surgical group significantly exceeded that of the surgical group [249]. Analyses of older patients (> 75 years) failed to show the same benefit in cancer-specific mortality for surgical treatment [251-253].

7.1.4.2 Surveillance

Elderly and comorbid patients with incidental small renal masses have a low RCC-specific mortality and significant competing-cause mortality [254, 255]. Active surveillance is defined as the initial monitoring of tumour size by serial abdominal imaging (US, CT, or MRI) with delayed intervention reserved for tumours showing clinical progression during follow-up [256].

In the largest reported series of active surveillance, the growth of renal tumours was low and progression to metastatic disease was reported in a limited number of patients [257, 258].

A single-institutional comparative study evaluating patients aged ≥ 75 years showed decreased OS for those who underwent surveillance and nephrectomy relative to NSS for clinically T1 renal tumours; however, patients selected for surveillance were older with greater comorbidity. At multivariable analysis, management type was not associated with OS after adjusting for age, comorbidity, and other variables [254]. No statistically significant difference in OS and CSS were observed in another study of RN vs. PN vs. active surveillance for T1a renal masses with a follow-up of 34 months [259]. Overall, both short- and intermediate-term oncological outcomes indicate that in selected patients with advanced age and/or comorbidities, active surveillance is appropriate to initially monitor small renal masses, followed if required, by treatment for progression [256-258, 260-263].

A multicentre study assessed patient QoL undergoing immediate intervention vs. active surveillance. Patients undergoing immediate intervention had higher QoL scores at baseline, specifically for physical health. The perceived benefit in physical health persisted for at least 1 year following intervention. Mental health, which includes domains of depression and anxiety, was not adversely affected while on active surveillance [264].

7.1.4.3 Ablative therapies

7.1.4.3.1 Cryoablation

Cryoablation is performed using either a percutaneous or a laparoscopic-assisted approach. In comparative studies, there was no significant difference in the overall complication rates between laparoscopic and percutaneous cryoablation [265-267]. One comparative study reported similar OS, CSS, and RFS in 172 laparoscopic patients with a longer follow-up compared with 123 percutaneous patients with a shorter follow-up [266]. A shorter average length of hospital stay was found with the percutaneous technique [266, 267]. No studies compared surveillance strategies to cryoablation.

7.1.4.3.2 Cryoablation versus PN

Studies compared open, laparoscopic or robotic PN with percutaneous or laparoscopic cryoablation. Oncological outcomes were mixed, with some studies showing no difference in OS, CSS, RFS, DFS, local recurrence or progression to metastatic disease [268, 269], and some showing significant benefit for the PN techniques for some or all of these outcomes [270-273]. Not all studies reported all outcomes listed, and some were small and included benign tumours. No study showed oncological benefit for the cryoablation technique over PN.

Perioperative outcomes, complication rates and other quality of life measures were also mixed. Some studies found the length of hospital stay was shorter and surgical blood loss was less with cryoablation [268-270], while also finding no differences in other peri-operative outcomes, recovery times, complication rates or post-operative serum creatinine levels. Two studies [272, 273] reported specific Clavien rates, with mostly non-significant differences, which were mixed for intra-operative vs. post-operative complications. Estimated GFRs were not significantly different in two studies, but in favour of cryoablation in a third [271-273]. Estimates of new CKD were also mixed, with one study in favour of cryoablation [271], another strongly in favour of PN [272], and the third showing no difference [273]. One study compared PN with ablation therapy, either cryoablation or RFA [274], and showed significantly improved DSS at both 5 and 10 years for PN.

7.1.4.3.3 Radiofrequency ablation

RFA is performed laparoscopically or percutaneously. Three studies compared patients with T1a tumours treated by laparoscopic or percutaneous RFA [275-277]. Complications occurred in up to 29% of patients but were mostly minor. Complication rates were similar in patients treated laparoscopically or percutaneously. One study with a limited number of patients [277] found a higher rate of incomplete ablation in patients treated by percutaneous RFA. However, no differences in recurrence or CSS were found in the three comparative studies.

7.1.4.3.4 RFA versus PN

Most publications about RFA are retrospective cohort studies with a low number of patients and limited follow-up. Three studies retrospectively compared RFA to surgery in patients with T1a tumours [201, 278, 279].

One study [278] compared T1a patients who underwent either RFA (percutaneous or laparoscopic) or partial nephrectomy and found no difference in OS and CSS. Another study retrospectively reviewed 105 T1a patients treated by percutaneous RFA or radical nephrectomy. CSS was 100% in both groups. OS was lower in the RFA group but patients treated with surgery were younger [201].

In a monocentric study that compared 34 RFA patients to 16 open partial nephrectomy patients, there was a higher rate of complications and transfusions in the PN group. Although the tumours were larger in PN patients, progression rates were similar (0%) [279].

7.1.4.3.5 Cryoablation versus RFA

Two studies compared RFA and cryoablation [280, 281]. No significant differences were reported for OS, CSS, or RFS in either study. For local RFS at 5 years, one study [280] reported improvement with RFA, while the other [281] reported a benefit with cryoablation. One study [280] reported no differences in Clavien complication rates between the techniques.

7.1.4.3.6 Other ablative techniques

Some studies have shown the feasibility of other ablative techniques, such as microwave ablation, laser ablation, and high-intensity focused US ablation. However, these techniques are considered experimental.

7.1.4.3.7 Conclusions and recommendations

Conclusions	LE
Population-based analyses show a significantly lower cancer-specific mortality for patients treated with surgery compared to non-surgical management. However, the same benefit in cancer-specific mortality is not confirmed in analyses focusing on older patients (> 75 years).	3
In active surveillance cohorts, the growth of small renal masses is low in most cases and progression to metastatic disease is rare (1-2%).	3
Quality of the available data does not allow definitive conclusions regarding morbidity and oncological outcomes of cryoablation and RFA.	3
Low quality studies suggest a higher local recurrence rate for minimally invasive therapies compared to PN.	3

Recommendations	GR
Due to the low quality of available data no recommendation can be made on RFA and cryoablation.	C
In the elderly and/or comorbid patients with small renal masses and limited life expectancy, active surveillance, RFA and cryoablation can be offered.	C

7.2 Treatment of locally advanced RCC

7.2.1 Introduction

In addition to the conclusions and recommendations outlined in Section 7.1 for localised RCC certain therapeutic strategies arise in specific situations of locally advanced disease.

7.2.2 Management of clinically positive lymph nodes (cN+)

In the presence of clinically positive LNs (cN+), LND is always justified [34]. However, the extent of LND is controversial [205].

7.2.3 Management of locally advanced unresectable RCC

In patients with non-resectable disease, embolisation can control symptoms, including gross haematuria or flank pain [222-224]. The use of neoadjuvant targeted therapy to downsize tumours is experimental and cannot be recommended outside controlled clinical trials.

7.2.4 Management of RCC with venous thrombus

Tumour thrombus formation in the IVC in RCC patients is a significant adverse prognostic factor. Traditionally, patients with venous tumour thrombus (VTT) undergo surgery to remove the kidney and tumour thrombus (TT). Aggressive surgical resection is widely accepted as the default management option for patients with VTT [282-290]. However, uncertainties remain over the best approach for surgical treatment of these patients.

7.2.4.1 The evidence base for surgery in patients with VTT

The data on whether patients with VTT should undergo surgery is derived from case series. In one of the largest published studies [287] a higher level of thrombus was not associated with increased tumour dissemination to LNs, perinephric fat or distant metastasis. Thus, all patients with non-metastatic disease and VTT, and an acceptable performance status (PS), should be considered for surgical intervention, irrespective of the extent of TT at presentation (LE: 3). The surgical technique and approach for each case should be selected based on the extent of TT (LE: 3).

7.2.4.2 The evidence base for different surgical strategies

A systematic review was undertaken which included comparison-only studies on the management of VTT in non-metastatic RCC [174]. Only 5 studies were eligible for final inclusion. There were high risks of bias across all studies.

Minimal access techniques resulted in significantly shorter operating time compared with traditional median sternotomy [291, 292]. Pre-operative embolisation [293] was associated with increased operating time, blood loss, hospital stay and peri-operative mortality in patients with T3 RCC.

No significant differences in oncological and process outcomes were observed between cardiopulmonary bypass with deep hypothermic circulatory arrest or partial bypass under normothermia or single caval clamp without circulatory support [294].

No surgical method was shown to be superior for the excision of VTT. The surgical method was dependent on the level of TT, and the grade of occlusion of the IVC [291, 292, 294]. The relative benefits and harms of other strategies and approaches regarding access to the IVC and the role of IVC filters and bypass procedures remain uncertain.

7.2.4.3 Conclusions and recommendations

Conclusions	LE
In patients with locally advanced disease due to clinically enlarged LNs the survival benefit of LND is unclear. In these cases LND can be performed for staging purposes.	3
Low quality data suggest that tumour thrombus in non-metastatic disease should be excised.	3
Tumour embolisation or IVC filter do not appear to offer any benefits.	3

Recommendations	GR
In patients with clinically enlarged LNs, LND can be performed for staging purposes or local control.	C
Excision of the kidney tumour and caval thrombus is recommended in patients with non-metastatic RCC.	C

7.2.5 Adjuvant therapy

Confirmation is needed regarding the impact on OS of adjuvant tumour vaccination in selected patients undergoing nephrectomy for T3 renal carcinomas [295-299] (LE: 1b). Several RCTs of adjuvant sunitinib, sorafenib, pazopanib, axitinib and everlimus are ongoing. At present, there is no evidence for the use of adjuvant VEGF-R or mTOR inhibitors.

7.2.5.1 Conclusion and recommendation

Conclusions	LE
Adjuvant cytokines do not improve survival after nephrectomy.	1b

Recommendations	GR
Outside controlled clinical trials, there is no indication for adjuvant therapy following surgery.	A

7.3 Advanced/metastatic RCC

7.3.1 Local therapy of advanced/metastatic RCC

7.3.1.1 Cytoreductive nephrectomy

Tumour nephrectomy is curative only if all tumour deposits are excised. This includes patients with the primary tumour in place and single- or oligo-metastatic resectable disease. For most patients with metastatic disease, cytoreductive nephrectomy (CN) is palliative and systemic treatments are necessary. In a meta-analysis comparing CN + immunotherapy versus immunotherapy only, increased long-term survival was found in patients treated with CN [300]. Only retrospective non-comparative data for CN combined with targeting

agents, such as sunitinib, sorafenib and others are available. CN is currently recommended in mRCC patients with good PS, large primary tumours and low metastatic volume. In patients with poor PS or IMDC risk, those with small primaries and high metastatic volume and/or a sarcomatoid tumour CN is not recommended.

7.3.1.1.1 Embolisation of the primary tumour

In patients unfit for surgery, or with non-resectable disease, embolisation can control symptoms, including gross haematuria or flank pain [222-224] (see recommendation Section 7.1.2.2.4).

7.3.1.1.2 Conclusions and recommendation

Conclusions	LE
Cytoreductive nephrectomy combined with interferon-alpha improves survival in patients with mRCC and good performance status.	1a
Cytoreductive nephrectomy for patients with simultaneous complete resection of a single metastasis or oligometastases may improve survival and delay systemic therapy.	3

Recommendations	GR
Cytoreductive nephrectomy is recommended in appropriately selected patients with metastatic RCC.	C

7.3.2 Local therapy of metastases in mRCC

A systematic review of the local treatment of metastases from RCC in any organ was undertaken [301]. Interventions included metastasectomy, various radiotherapy modalities, and no local treatment. The outcomes were OS, CSS and PFS, local symptom control and adverse events. A risk-of-bias assessment was conducted [302]. Of 2,235 studies identified only 16 non-randomised comparative studies were included.

Eight studies reported on local therapies of RCC-metastases in various organs [303-310]. This included metastases to any single organ or multiple organs. Three studies reported on local therapies of RCC-metastases in bone, including the spine [311-313], two in the brain [314, 315] and one each in the liver [316] lung [317] and pancreas [318]. Three studies [307, 309, 317] were abstracts. Data were too heterogenous for a meta-analysis. There was considerable variation in the type and distribution of systemic therapies (cytokines and VEGF-inhibitors) and in reporting the results.

7.3.2.1 Complete versus no/incomplete metastasectomy

All eight studies [303-310] on RCC metastases in various organs compared complete versus no and/or incomplete metastasectomy. However, in one study [306], complete resections were achieved in only 45% of the metastasectomy cohort, which was compared with no metastasectomy. Non-surgical modalities were not applied. Six studies [303, 305-307, 309, 310] reported a significantly longer median OS or CSS following complete metastasectomy (the median value for median OS or CSS was 40.75 months, range 23-122 months) compared with incomplete and/or no metastasectomy (the median value for median OS or CSS was 14.8 months, range 8.4-55.5 months). Of the two remaining studies, one [304] showed no significant difference in CSS between complete and no metastasectomy, and one [308] reported a longer median OS for metastasectomy albeit no p-value was provided.

Three studies reported on treatment of RCC metastases to the lung [317], liver [316], and pancreas [318], respectively. The lung study reported a significantly higher median OS for metastasectomy versus medical therapy only for both target therapy and immunotherapy. Similarly, the liver and pancreas study reported a significantly higher median OS and 5-year OS for metastasectomy versus no metastasectomy.

7.3.2.2 Local therapies for RCC bone metastases

Of three studies identified, one [313] compared single-dose image-guided radiotherapy (IGRT) with hypofractionated IGRT in patients with RCC bone metastases. Single-dose IGRT (≥ 24 Gray) had a significantly better 3-year actuarial local PFS rate, also shown by Cox regression analysis. Another study [311] compared metastasectomy/curettage and local stabilization with no surgery of solitary RCC bone metastases in various locations. A significantly higher 5-year CSS rate was observed in the intervention group.

After adjusting for prior nephrectomy, gender and age, multivariate analysis still favoured metastasectomy/curettage and stabilization. A third study [312] compared the efficacy and durability of pain relief between single-dose stereotactic body radiotherapy (SBRT) and conventional radiotherapy (CRT) in patients with RCC bone metastases to the spine. Pain ORR, time-to-pain relief and duration of pain relief were similar.

7.3.2.3 Local therapies for RCC brain metastases

Two studies on RCC brain metastases were included. A three-armed study [314] compared stereotactic radiosurgery (SRS) versus whole brain radiotherapy (WBRT) versus SRS + WBRT. Each group was further subdivided into recursive partitioning analysis (RPA) classes I to III (I favourable, II moderate and III poor patient status). Two-year OS and intracerebral control were equivalent in patients treated with SRS alone and SRS + WBRT. Both treatments were superior to WBRT alone in the general study population and in the RPA subgroup analyses. A comparison of SRS versus SRS + WBRT in a subgroup analysis of RPA class I showed significantly better 2-year OS and intracerebral control for SRS + WBRT based on only three participants. The other study [315] compared fractionated stereotactic radiotherapy (FSRT) with metastasectomy + CRT or CRT alone. Several patients in all groups underwent alternative surgical and non-surgical treatments after initial treatment. 1-, 2- and 3-year survival rates were higher but not significantly so for FSRT than for metastasectomy + CRT or CRT alone. FSRT did not result in a significantly better 2-year local control rate compared with MTS + CRT.

7.3.2.4 Embolisation of metastases

Embolisation prior to resection of hypervascular bone or spinal metastases can reduce intra-operative blood loss [319]. In selected patients with painful bone or paravertebral metastases, embolisation can relieve symptoms [320] (see recommendation Section 7.1.2.2.4)

7.3.2.5 Conclusions and recommendations

Conclusions	LE
All included studies were retrospective non-randomised comparative studies, resulting in a high risk of bias associated with non-randomization, attrition, and selective reporting.	3
With the exception of brain and possibly bone metastases, metastasectomy remains by default the most appropriate local treatment for most sites.	3
Retrospective comparative studies consistently point towards a benefit of complete metastasectomy in mRCC patients in terms of overall survival, cancer-specific survival and delay of systemic therapy.	3
Radiotherapy to bone and brain metastases from RCC can induce significant relief from local symptoms (e.g. pain).	3

Recommendations	GR
No general recommendations can be made. The decision to resect metastases has to be taken for each site, and on a case-by-case basis; performance status, risk profiles, patient preference and alternative techniques to achieve local control, must be considered.	C
In individual cases, stereotactic radiotherapy for bone metastases, and stereotactic radiosurgery for brain metastases can be offered for symptom relief.	C

7.4 Systemic therapy for advanced/metastatic RCC

7.4.1 Chemotherapy

Chemotherapy is moderately effective only if 5-fluorouracil (5-FU) is combined with immunotherapeutic agents [321]. However, in one study, interferon-alpha (IFN- α) showed equivalent efficacy to IFN- α + interleukin-2 (IL-2) + 5-FU [322].

7.4.1.1 Conclusion and recommendation

Conclusion	LE
In mRCC 5-FU combined with immunotherapy has equivalent efficacy to IFN- α .	1b

Recommendation	GR
In patients with clear-cell mRCC, chemotherapy is not considered effective.	B

7.4.2 Immunotherapy

7.4.2.1 IFN- α monotherapy and combined with bevacizumab

Conflicting results exist for IFN- α in clear-cell (cc) mRCC. Several studies showed that IFN- α in mRCC has a survival advantage similar to that of hormonal therapy [323]. IFN- α resulted in a response rate of 6-15%, a 25% decrease in tumour progression risk and a modest survival benefit compared to placebo [83, 324]. However, patients with intermediate-risk disease, failed to confirm this benefit [325].

IFN- α may only be effective in some patient subgroups, including patients with ccRCC, favourable-risk criteria, as defined by the Memorial Sloan-Kettering Cancer Center (MSKCC) and lung metastases only [324]. The moderate efficacy of immunotherapy was confirmed in a Cochrane meta-analysis [324]. Bevacizumab + IFN- α increased response rates and PFS in first-line therapy compared with IFN- α monotherapy [326]. All studies comparing targeted drugs to IFN- α monotherapy therapy showed superiority for sunitinib, bevacizumab + IFN- α , and temsirolimus [326-329]. IFN- α has been superseded by targeted therapy in cc-mRCC.

Table 7.1: MSKCC (Motzer) criteria [83]

Risk factors*	Cut-off point used
Karnofsky PS	< 80
Time from diagnosis to treatment	< 12 months
Haemoglobin	< Lower limit of laboratory reference range
LDH	> 1.5 times the upper limit of laboratory range
Corrected serum calcium	> 10.0 mg/dL (2.4 mmol/L)

* Favourable (low) risk, no risk factors; intermediate risk, one or two risk factors; poor (high) risk, three or more risk factors.

7.4.2.2 Interleukin-2

IL-2 has been used to treat mRCC since 1985, with response rates ranging from 7% to 27% [329-331]. Complete responses have been achieved with high-dose bolus IL-2 [332]. The toxicity of IL-2 is substantially greater than that of IFN- α , ranging from 7% to 27% [324].

7.4.2.3 Vaccines and targeted immunotherapy

A vaccine trial with tumour antigen 5T4 + first-line standard therapy (i.e. sunitinib, IL-2 or IFN- α) showed no survival benefit compared with placebo and first-line standard therapy [333]. Several vaccination studies are ongoing. Monoclonal antibodies against programmed death-1 (PD-1) or its ligand (PD-1L), which have efficacy and acceptable toxicity in patients with RCC [334], are currently investigated in phase III trials, as first- and second line.

7.4.2.4 Conclusions and recommendations

Conclusions	LE
IFN- α monotherapy is inferior to targeted therapy in MRCC.	1b
IL-2 monotherapy may have a role in selected cases (good PS, ccRCC, lung metastases only).	2
IL-2 has more side-effects than IFN- α .	2-3
High dose IL-2 is associated with durable complete responses in a limited number of patients. However, no clinical factors or biomarkers exist to accurately predict a durable response in patients treated with HD-IL2.	1b
Bevacizumab plus IFN- α is more effective than IFN- α in treatment-naïve, low-risk and intermediate-risk tumours.	1b
Vaccination therapy with tumour antigen 5T4 showed no survival benefit over first-line standard therapy.	1b
Cytokine combinations, with or without additional chemotherapy, do not improve OS compared with monotherapy.	1b

Recommendation	GR
Monotherapy with IFN- α or HD bolus IL-2 is not routinely recommended as first-line therapy in mRCC.	A

7.4.3 Targeted therapies

In sporadic ccRCC, hypoxia-inducible factor (HIF) accumulation due to von Hippel-Lindau (VHL) inactivation results in overexpression of vascular endothelial growth factor (VEGF and platelet-derived growth factor (PDGF), which promote neoangiogenesis [335-337]. This process substantially contributes to the development and progression of RCC. There are several targeting drugs approved for treating mRCC in both the USA and Europe:

- sorafenib (Nexavar®);

- sunitinib (Sutent®);
- bevacizumab (Avastin®) combined with IFN- α ;
- pazopanib (Votrient®);
- temsirolimus (Torisel®);
- everolimus (Afinitor®);
- axitinib (Inlyta®).

Most published trials have selected for clear-cell carcinoma subtypes, thus no robust evidence-based recommendations can be given for non-ccRCC subtypes.

In major trials leading to registration of the approved targeted agents, patients were stratified according to the MSKCC risk model [323] (Table 7.1). Since the MSKCC (Motzer) criteria were developed during the cytokine era, the International Metastatic Renal Cancer Database Consortium (IMDC) risk model has been established and validated to yield an accurate prognosis for patients treated in the era of targeted therapy. Neutrophilia and thrombocytosis have been added to the list of MSKCC risk factors, while LDH has been removed [338].

The IMDC published data on conditional survival which may be used in patient counselling [339]. The IMDC risk model has been validated and compared with the Cleveland Clinic Foundation (CCF) model, the French model, MSKCC model, and the International Kidney Cancer Working Group (IKCWG) model. The IMDC model did not differ from the other models, indicating that a ceiling has been reached in predicting prognosis based solely on clinical factors [340].

Table 7.2: Median OS and patients surviving 2 years treated in the era of targeted therapy per IMDC risk group (based on references [338, 340])

IMDC Model ***	Patients**	Median OS* (months)	2-y OS (95% CI) **	
	n	%		
Favourable	157	18	43.2	75% (65-82%)
Intermediate	440	52	22.5	53% (46-59%)
Poor	252	30	7.8	7% (2-16%)

* Based on [340]; ** based on [338]; CI = confidence interval; OS = overall survival.

7.4.3.1 Tyrosine kinase inhibitors

7.4.3.1.1 Sorafenib

Sorafenib is an oral multikinase inhibitor. A trial compared sorafenib and placebo after failure of prior systemic immunotherapy or in patients unfit for immunotherapy. Sorafenib improved PFS [341] (HR: 0.44; 95% CI: 0.35-0.55; $p < 0.01$). OS improved in patients who crossed over from placebo to sorafenib [342]. In patients with previously untreated mRCC sorafenib was not superior to IFN- α . A number of studies have used sorafenib as the control arm in sunitinib-refractory disease versus axitinib, dovitinib and temsirolimus. None showed superior survival compared to sorafenib.

7.4.3.1.2 Sunitinib

Sunitinib is an oral tyrosine kinase (TK) inhibitor and has antitumour and anti-angiogenic activity. Sunitinib as second-line monotherapy in patients with mRCC demonstrated a partial response in 34-40% and stable disease > 3 months in 27-29% of patients [343]. First-line monotherapy with sunitinib demonstrated longer PFS compared with IFN- α . OS was greater in patients treated for 26.4 and 21.8 months with sunitinib despite crossover [344].

In the EFFECT trial, sunitinib 50 mg/day (4 weeks on/2 weeks off) was compared with continuous uninterrupted sunitinib 37.5 mg/day in patients with clear-cell mRCC [345]. Median time to progression (TTP) with sunitinib 50 mg was numerically longer than the 37.5 mg arm (9.9 months versus 7.1 months). No significant differences in OS were seen (23.1 vs. 23.5 months; $p = 0.615$). Toxicity was comparable in both arms. Because of the non-significant, but numerically longer TTP with the standard 50 mg dosage, the authors recommended using this regimen. Alternate scheduling of sunitinib (2 weeks on/1 week off) is being used to manage toxicity.

7.4.3.1.3 Pazopanib

Pazopanib is an oral angiogenesis inhibitor. In a trial of pazopanib versus placebo in treatment-naïve mRCC patients and cytokine-treated patients, a significant improvement in PFS and tumour response was observed

[346]. Median PFS with pazopanib compared with placebo was:

- 9.2 vs. 4.2 months in the overall study population;
- 11.1 vs. 2.8 months for the treatment-naïve subpopulation;
- 7.4 vs. 4.2 months for the cytokine-pretreated subpopulation.

A trial comparing pazopanib with sunitinib (COMPARZ) established pazopanib as another first-line option. It showed that pazopanib was not associated with significantly worse PFS or OS compared to sunitinib. The two drugs had different toxicity profiles [347], and QoL was better with pazopanib. In another patient-preference study (PISCES), patients preferred pazopanib to sunitinib due to symptomatic toxicity [348]. Both studies were limited in that intermittent therapy (sunitinib) was compared with continuous therapy (pazopanib).

7.4.3.1.4 Axitinib

Axitinib is an oral selective second-generation inhibitor of VEGFR-1, -2, and -3. Axitinib was first evaluated as second-line treatment. In the AXIS trial (axitinib versus sorafenib in patients with previously failed cytokine treatment or targeted agents), the sample size calculation was based on a 40% improvement in median PFS from 5-7 months in patients receiving axitinib [349].

The overall median PFS was greater for axitinib than sorafenib. The difference in PFS was greatest in patients in whom cytokine treatment had failed. For those in whom sunitinib had failed, axitinib was associated with a greater PFS than sorafenib (4.8 vs. 3.4 months). Axitinib showed > grade 3 diarrhoea in 11%, hypertension in 16%, and fatigue in 11%. Across all grades, nausea was recorded in 32%, vomiting in 24%, and asthenia in 21%. OS was a secondary end-point of the trial in which crossover was not permitted. Final analysis of OS showed no significant differences between the groups in second-line treatment [350, 351].

Axitinib was investigated in two first-line studies [352, 353]. One investigated the efficacy and safety of axitinib dose titration in previously untreated patients with mRCC. Although the objective RR was higher in patients treated to toxicity, median PFS was 14.5 months in the axitinib titration group, 15.7 months in the placebo titration group, and 16.6 months in nonrandomised patients [352]. This supports the hypothesis that dose escalation is associated with higher RRs.

In a trial of axitinib vs. sorafenib in first-line treatment-naïve cc-mRCC, a significant difference in median PFS between the treatment groups was not demonstrated [353]. As a result of this study, axitinib is not approved for first-line therapy.

7.4.4 **Monoclonal antibody against circulating VEGF**

7.4.4.1 *Bevacizumab monotherapy and bevacizumab + IFN- α*

Bevacizumab is a humanised monoclonal antibody. The AVOREN study compared bevacizumab + IFN- α with IFN- α monotherapy in mRCC [326]. Median OR was higher in the bevacizumab + IFN- α group. Median PFS increased from 5.4 months with IFN- α to 10.2 months with bevacizumab + IFN- α . No benefit was seen in MSKCC poor-risk patients. Median OS in this trial, which allowed crossover after progression, was not greater in the bevacizumab-IFN- α group (23.3 vs. 21.3) [354].

A similarly designed trial (CALGB 90206) [355, 356], of bevacizumab + IFN- α vs. IFN- α showed a higher median PFS for the combination group. ORR was also higher in the combination group. Overall toxicity was greater for bevacizumab + IFN- α , with significantly more grade 3 hypertension, anorexia, fatigue, and proteinuria.

7.4.5 **mTOR inhibitors**

7.4.5.1 *Temsirolimus*

Temsirolimus is a specific inhibitor of mTOR [357]. Patients with modified high-risk mRCC in the NCT00065468 trial received first-line temsirolimus or IFN- α monotherapy, or a combination of both [328]. Median OS was higher in the temsirolimus group. However, OS in the temsirolimus + IFN- α group was not significantly superior to IFN- α alone [328]. IFN- α toxicity was marked, partly due to the high doses used. The INTORSECT trial investigated temsirolimus vs. sorafenib in patients who had previously failed sunitinib. Although no benefit in PFS was observed, a significant OS benefit for sorafenib was noted [358]. Based on these results, temsirolimus is not recommended in patients with VEGF TKI refractory disease.

7.4.5.2 *Everolimus*

Everolimus is an oral mTOR inhibitor, which is established in the treatment of VEGF-refractory disease. The RECORD-1 study compared everolimus + best supportive care (BSC) vs. placebo + BSC in patients with previously failed anti-VEGFR treatment (or previously intolerant of VEGF targeted therapy) [359]. The initial data showed a median PFS of 4.0 months v.s. 1.9 months for everolimus and placebo, respectively [359]. This

was extended to 4.9 months in the final analysis HR=0.33 [360]. Subset analysis of PFS for patients receiving only 1 previous VEGF TKI was 5.4 months [361]. This included some patients who were intolerant rather than progressed on therapy (PFS also 5.4 months) [362]. RECORD-1 included patients who failed multiple lines of VEGF-targeted therapy, and received everolimus in third- and fourth-line setting [359].

The RECORD-3 study of sunitinib vs. everolimus in treatment-naïve mRCC followed by either sunitinib or everolimus upon progression reported a higher median PFS for first-line treatment in the sunitinib group [363]. A large number of the crossover patients did not receive the planned subsequent therapy making further analysis complex and underpowered. Survival in the sunitinib-followed-by-everolimus-arm was high, mature analysis is awaited.

7.4.6 Therapeutic strategies and recommendations

7.4.6.1 Therapy for treatment-naïve patients with clear-cell mRCC

Pivotal trials have established sunitinib and bevacizumab plus IFN- α as first-line treatment options in treatment-naïve patients with cc-mRCC and a favourable-to-intermediate risk score. The COMPARZ study demonstrated that pazopanib and sunitinib have similar efficacy and different toxicity profiles. This study firmly establishes pazopanib as another first-line option [347].

7.4.6.1.1 Sequencing targeted therapy

7.4.6.1.1.1 Following progression of disease with VEGF-targeted therapy

Several trials investigated therapeutic options for patients who progressed on first-line VEGF-targeted therapy. RECORD-1 established VEGF TKI until disease progression followed by everolimus as one of the treatment options for patients with mRCC [359]. AXIS was the only trial to compare two TKIs after failure of a prior TKI. The results and interpretation are described under 7.3.1.4 above [349-351]. Comparison of RECORD-1 data with AXIS data is not advised due to differences in patient populations [349-351, 359].

INTORSECT was the only trial to directly compare an mTOR inhibitor and TKI (temsirolimus vs. sorafenib) after disease progression on sunitinib [358]. Median PFS was higher, but not significant, in the temsirolimus group. However, there was a significant difference in OS in favour of sorafenib. These data are not necessarily relevant to other mTOR inhibitors such as everolimus.

No firm recommendations can currently be made as to the best sequence of targeted therapy. However, VEGF-targeted therapy should be used for patients with favourable- and intermediate-risk disease in the first-line setting.

7.4.6.1.1.2 Treatment after progression of disease with mTOR inhibition

There are limited data addressing this issue. In view of the efficacy of VEGF-targeted therapy in renal cancer, a switch to VEGF-targeted therapy is advised (expert opinion and [364].

7.4.6.1.1.3 Treatment after progression of disease with cytokines

Trials have established sorafenib, axitinib and pazopanib as therapeutic options in this setting with a median PFS of 5.5, 12.1 and 7.4 months, respectively. Based on trial data, axitinib is superior to sorafenib in patients previously treated with cytokine therapy [349-351].

7.4.6.1.1.4 Treatment after second-line targeted therapy

The RECORD-1 study demonstrated the activity of everolimus in patients who had received more than one line of targeted therapy. 26% of patients were treated with two or more lines of VEGF-targeted therapy and significant benefits were seen. Although the GOLD trial failed to demonstrate superior efficacy of dovitinib over sorafenib in patients with mRCC who experienced disease progression after receiving prior VEGF- and mTOR-targeted therapies, the results suggest efficacy and safety of sorafenib in the third-line setting [364].

7.4.6.1.1.5 Combination of targeted agents

There have been a number of trials with VEGF targeted therapy and mTOR inhibitors [365-369]. The results have all been negative. No combinations of targeted agents are currently recommended.

7.4.6.2 Non-clear-cell renal cancer

No phase III trials of patients with non-clear-cell RCC have been reported. Expanded access programmes and subset analysis from RCC studies suggest the outcome of these patients with targeted therapy is poorer than for ccRCC. Targeted treatment in non-clear-cell RCC has focused on temsirolimus, everolimus, sorafenib and sunitinib [328, 370-372].

The most common non-clear-cell subtypes are papillary type 1 and 2 RCCs. There are small single-arm data for sunitinib and everolimus [372-375]. A trial of both types of papillary RCC treated with everolimus (RAPTOR) [375], showed median PFS of 3.7 months per central review in the intention-to-treat population with a median OS of 21.0 months.

Another trial investigated foretinib (a dual MET/VEGFR2 inhibitor) in patients with papillary RCC. Toxicity was acceptable with a high RR in patients with germline MET mutations [376]. However, a randomised phase II trial of everolimus vs. sunitinib with crossover design in non-clear-cell mRCC included 73 patients (27 with papillary RCC) and was stopped after a futility analysis for PFS and OS. Median OS for everolimus was 10.5 months but not reached for sunitinib [377]. The final results presented at the 2014 annual meeting of the American Society of Clinical Oncology showed a nonsignificant trend favouring sunitinib. Both sunitinib and everolimus remain options in this population, with a preference for sunitinib. Patients with ncc-mRCC should be referred to a clinical trial where appropriate.

Collecting-duct cancers are resistant to systemic therapy. There is a lack of data to support specific therapy in these patients. There is limited data supporting the use of targeted therapy in other histological subtypes such as chromophobe tumours [328, 370].

Table 7.3: EAU 2015 evidence-based recommendations for systemic therapy in patients with mRCC

RCC type	MSKCC risk group [323]	First-line	LE [^]	Second-line*	LE [^]	Third-line*	LE [^]	Later lines	LE
Clear cell*	Favourable, Intermediate and poor	sunitinib pazopanib bevacizumab + IFN Favourable-intermediate only)	1b 1b 1b	after VEGFR: axitinib sorafenib# everolimus after cytokines: sorafenib# axitinib pazopanib	 2a 2a 2a 1b 2a 2a	after VEGFR: everolimus after mTOR: sorafenib	 2a 1b	any targeted agent	4

<p><i>IFN-α = interferon alpha; LE = level of evidence; MSKCC = Memorial Sloan-Kettering Cancer Center; mTOR = mammalian target of rapamycin inhibitor; RCC = renal cell carcinoma; TKI= tyrosine kinase inhibitor.</i></p> <p>* Doses: IFN-α - 9 MU three times per week subcutaneously, bevacizumab 10 mg/kg biweekly intravenously; sunitinib 50 mg daily orally for 4 weeks, followed by 2 weeks of rest (37.5 mg continuous dosing did not show significant differences); temsirolimus 25 mg weekly intravenously; pazopanib 800 mg daily orally. Axitinib 5 mg twice daily, to be increased to 7 mg twice daily, unless greater than grade 2 toxicity, blood pressure higher than 150/90 mmHg, or the patient is receiving antihypertensive medication. Everolimus, 10 mg daily orally.</p> <p>§ No standard treatment available. Patients should be treated in the framework of clinical trials or a decision can be made in consultation with the patient to perform treatment in line with ccRCC.</p> <p>¶ Poor risk criteria in the NCT00065468 trial consisted of MSKCC [323] risk plus metastases in multiple organs.</p> <p># Sorafenib was inferior to axitinib in a RCT in terms of PFS but not OS [351].</p> <p>^ Level of evidence was downgraded in instances when data were obtained from subgroup analysis within an RCT.</p>									

7.4.6.3 Conclusions and recommendations for systemic therapy in mRCC

Conclusions	LE
TKIs increase PFS and/or OS as both first-line and second-line treatments for clear-cell mRCC.	1b
Axitinib has proven efficacy and superiority in PFS as a second-line treatment after failure of cytokines and VEGF-targeted therapy in comparison with sorafenib.	1b
Sunitinib is more effective than IFN- α in treatment-naïve patients.	1b
Bevacizumab plus IFN- α is more effective than IFN- α in treatment-naïve low-risk and intermediate-risk patients.	1b
Pazopanib is superior to placebo in both naïve mRCC patients and post-cytokine patients.	1b
Pazopanib is not inferior to sunitinib in clear-cell mRCC patients.	1b
Temsirolimus monotherapy prolongs OS compared to IFN- α in poor-risk mRCC.	1b
Everolimus prolongs PFS in patients who have previously failed or are intolerant of VEGF-targeted therapy.	1b
Sorafenib has broad activity in a spectrum of settings in clear-cell patients previously treated with cytokine or targeted therapies.	4
Both mTOR inhibitors (everolimus and temsirolimus) and VEGF-targeted therapies (sunitinib or sorafenib) can be used in non-clear-cell RCC.	3
No combination has proven to be better than single-agent therapy.	1a

Recommendations	GR
Systemic therapy for mRCC should be based on targeted agents.	A
Sunitinib and pazopanib are recommended as first-line therapy for advanced/metastatic clear-cell RCC.	A
Bevacizumab + IFN- α recommended as first-line therapy for advanced/metastatic RCC in favourable-risk and intermediate-risk ccRCC.	A
Temsirolimus is recommended as first-line treatment in poor-risk RCC patients.	A
Axitinib is recommended as second-line treatment for mRCC.	A
Everolimus is recommended for ccRCC patients who have failed VEGF-targeted therapy.	A
Pazopanib and sorafenib are alternatives to axitinib and are recommended as second-line therapy after failure of prior cytokines.	B
Sequencing of targeted agents is recommended.	A
Sunitinib can be recommended as first-line therapy for non-clear-cell mRCC.	B

7.5 Recurrent RCC

7.5.1 Introduction

Locally recurrent disease can occur either after partial nephrectomy, nephrectomy and thermal ablation. After nephron sparing treatment approaches the recurrence may be intrarenal or in addition regional, e.g. venous tumour thrombi or retroperitoneal lymph node metastases. Both are often summarised as locoregional recurrences. Recurrence rates for pT1 tumours after partial nephrectomy are observed in 2.2% and are generally managed surgically depending on the extent of the locoregional recurrence [378]. After thermal ablation locoregional recurrences (intrarenal and regional) have been described in up to 12% [379]. Repeated ablation has often been recommended for intrarenal recurrences following thermal ablation. For locoregional recurrences surgical resection is mandatory as has been described for isolated local recurrences following nephrectomy.

After nephrectomy locally recurrent disease is defined as recurrent disease in the former kidney rest. However, metastasis in the not removed ipsilateral adrenal or non-resected lymph nodes makes interpretation of the true incidence of isolated recurrence in the renal fossa difficult. Treatment of adrenal metastases or lymph node metastases are often described in series of metastasectomy (Section 7.3). Isolated local recurrence however is rare.

The largest series on the treatment of isolated recurrence was published in 2009 [380]. Of 2,945 patients who underwent nephrectomy the authors identified 54 isolated local recurrences in the renal fossa. These however included those to the ipsilateral adrenal and lymph nodes. Exclusively retrospective non-comparative data exist which suggest that aggressive local resection offers durable local tumour control and improves survival. Adverse prognostic factors were a positive surgical margin after resection, the size of the recurrence and sarcomatoid histologic features [380]. In cases where complete surgical removal is not feasible due to advanced tumour growth and pain, palliative treatments including radiation treatment can be considered.

Conclusions	LE
Isolated recurrence in the local renal fossa is rare.	3
Patients with resectable local recurrences and absent sarcomatoid features may benefit from resection.	3

Recommendation	GR
Surgical resection of local recurrent disease may result in durable local control and improved survival	C

8. FOLLOW-UP AFTER RADICAL NEPHRECTOMY OR PARTIAL NEPHRECTOMY OR ABLATIVE THERAPIES FOR RCC

8.1 Introduction

Surveillance after treatment for RCC allows the urologist to monitor or identify:

- Postoperative complications
- Renal function
- Local recurrence after PN or ablative treatment
- Recurrence in the contralateral or ipsilateral (after PN) kidney
- Development of metastases

The method and timing of examinations have been the subject of many publications. There is no consensus on surveillance after RCC treatment, and there is no evidence that early vs. later diagnosis of recurrences improves survival. However, follow-up is important to increase the available information on RCC, and should be performed by the urologist, who should record the time to recurrence or the development of metastases. Postoperative complications and renal function are readily assessed by the patient's history, physical examination, and measurement of serum creatinine and eGFR. Repeated long-term monitoring of eGFR is indicated if there is impaired renal function before surgery, or postoperative deterioration. Renal function [381, 382] and non-cancer survival [180-182] can be optimised by performing NSS whenever possible for T1 and T2 tumours [383] (LE: 3). Tumour-bed recurrence is rare, but early diagnosis is useful, as the most effective treatment is cytoreductive surgery [384, 385]. Recurrence in the contralateral kidney is also rare and is related to positive margins, multifocality, and grade [386] (LE: 3). Surveillance can identify local recurrences or metastases at an early stage. This is particularly important with ablative therapies such as cryotherapy and RFA. Although the local recurrence rate is higher than after conventional surgery, the patient may still be cured using repeat ablative therapy or RN [387] (LE: 3). In metastatic disease, extended tumour growth can limit the opportunity for surgical resection, considered the standard therapy in cases of resectable and preferably solitary lesions. In addition, early diagnosis of tumour recurrence may enhance the efficacy of systemic treatment if the tumour burden is low.

8.2 Which investigations for which patients, and when?

Intensive radiological surveillance for all patients is unnecessary. The outcome after surgery for T1a low-grade tumours is almost always excellent. It is therefore reasonable to stratify the follow-up, taking into account the risk of developing recurrence or metastases. Although there is no randomised evidence, large studies have examined prognostic factors with long follow-up periods, from which conclusions can be drawn [31, 388, 389] (LE: 4):

- The sensitivity of chest radiography for small metastases is poor and US has limitations. Surveillance should not be based on these imaging modalities [390]. With low-risk tumours, surveillance intervals should be adapted relative to radiation exposure and benefit. To reduce radiation exposure, MRI can be used.
- When the risk of relapse is intermediate or high, CT of the chest and abdomen should be performed, although significant morbidity associated with the radiation exposure involved in repeated CT scans should be taken into account [391]. CT can clearly reveal metastatic lesions from RCC [392].
- Surveillance should also include clinical evaluation of renal function and cardiovascular risk factors.

- Positron-emission tomography (PET) and PET-CT as well as bone scintigraphy are not the standard of care in RCC surveillance, due to limited specificity and sensitivity.
- Depending on the availability of effective new treatments, more strict follow-up schedules may be required, particularly as there is a higher local recurrence rate after cryotherapy and RFA.

There is controversy over the optimal duration of follow-up. Some argue that follow-up with imaging is not cost-effective after 5 years; however, late metastases are more likely to be solitary and justify more aggressive therapy with curative intent. In addition, patients with tumours that develop in the contralateral kidney can be treated with NSS if the tumours are detected when small. For tumours < 4 cm, there is no difference between PN and RN with regard to recurrences during follow-up [189] (LE: 3).

Several authors [165, 167, 393, 394], have designed scoring systems and nomograms to quantify the likelihood of patients developing tumour recurrences, metastases, and subsequent death. These systems have been compared and validated [395] (LE: 2). Using prognostic variables, several stage-based surveillance regimens have been proposed [396, 397], but do not include ablative therapies. A postoperative nomogram is available for estimating the likelihood of freedom from recurrence at 5 years [162]. Recently, a preoperative prognostic model based on age, symptoms, and TNM staging has been published and validated [171] (LE: 3). A surveillance algorithm for monitoring patients after treatment for RCC is needed, recognising not only the patient risk profile, but also efficacy of the treatment given (Table 8.1).

Table 8.1: Proposed surveillance schedule following treatment for RCC, taking into account patient risk profile and treatment efficacy

Risk profile	Treatment	Surveillance						
		6 mo	1 y	2 y	3 y	4 y	5 y	> 5 y
Low	RN/PN only	US	CT	US	CT	US	CT	Discharge
Intermediate	RN/PN/cryo/ RFA	CT	CT	CT	US	CT	CT	CT once every 2 years
High	RN/PN/cryo/ RFA	CT	CT	CT	CT	CT	CT	CT once every 2 years

Cryo = cryotherapy; CT = computed tomography of chest and abdomen, or MRI = magnetic resonance imaging; PN = partial nephrectomy; RFA = radiofrequency ablation; RN = radical nephrectomy; US = ultrasound of abdomen, kidneys and renal bed.

8.3 Conclusions and recommendations for surveillance following RN or PN or ablative therapies in RCC

Conclusions	LE
Surveillance can detect local recurrence or metastatic disease while the patient is still surgically curable. Renal function should be assessed.	4
Risk stratification should be based on preexisting classification systems such as the UISS integrated risk assessment score (http://urology.ucla.edu/body.cfm?id=443 [163]).	4

Recommendations	GR
Follow-up after treatment for RCC should be based on a patient's risk factors and type of treatment.	C
For low-risk disease, CT/MRI can be used infrequently.	C
In intermediate-risk patients, intensified follow-up should be performed, including CT/MRI scans at regular intervals in accordance with a risk-stratified nomogram.	C
In high-risk patients, the follow-up examinations should include routine CT/MRI scans.	C
There is an increased risk of intrarenal recurrences in larger (> 7 cm) tumours treated with NSS, or when there is a positive margin. Follow-up should be intensified in these patients.	C

8.4 Research priorities

There is a clear need for future research to determine whether follow-up can optimise patient survival. Further information should be sought at what time point restaging has the highest chance to detect recurrence. Prognostic markers at surgery should be investigated to determine the risk of relapse over time.

10. CONFLICT OF INTEREST

All members of the Renal Cell Cancer working group have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: <http://www.uroweb.org/guidelines/>. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

1. INTRODUCTION

1.1 Aims and scope

The aim of these guidelines is to present the current evidence for the diagnosis and treatment of patients with cancer of the testis. Testicular cancer represents 5% of urological tumours affecting mostly younger males. This document addresses germ-cell tumours and sex cord/gonadal stromal tumours.

1.2 Panel composition

The EAU Guidelines Panel on Testicular Cancer consists of a multidisciplinary group of clinicians, including urologists, a pathologist, oncologists and radiotherapists. Members of this panel have been selected based on their expertise to represent the professionals treating patients suspected of harbouring testis cancer.

1.2.1 Potential conflict of interest

All experts involved in the production of this document have submitted potential conflict of interest statements.

1.3 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text versions. Several scientific publications are available as are a number of translations of all versions of the EAU Testicular Cancer Guidelines. All documents can be viewed, free access, through the EAU website Uroweb: <http://www.uroweb.org/guidelines/online-guidelines/>.

1.4 Publication history and summary of changes

1.4.1 Publication history

The European Association of Urology (EAU) published the first guidelines on Testicular Cancer in 2001. Since 2008, the Testicular Guidelines contain a separate chapter on testicular stromal tumours. This document presents a limited update of the 2014 publication. Review papers have been published in the society scientific journal European Urology, the latest version dating to 2011 [1].

1.4.2 Summary of changes

The literature in the entire document has been assessed and updated, whenever relevant.

Key changes for this 2015 print:

- A new flowchart (Figure 2) on Treatment options in patient with seminoma clinical state IIA and IIB has been included.
- A new section on Quality of life and long-term toxicities after cure for testicular cancer was added (Section 8.6).

Conclusions and recommendations have been rephrased and added to throughout the current document.

Changed or new conclusions and recommendations can be found in sections:

5.9 Guidelines for the Diagnosis and staging of testicular cancer

Biopsy of the contralateral testis should be offered (and its consequences discussed) to patients at high risk for contralateral TIN.	A
---	---

TIN = testicular intraepithelial neoplasia.

7.3.6 Guidelines for the treatment of NSGCT stage I

CS1B (pT2-pT4): high risk	LE	GR
Primary chemotherapy with one course of BEP is recommended	2a	A*
Patients should be informed about the advantages and disadvantages of two courses of BEP.		

BEP = cisplatin, etoposide, and bleomycin.

Table 8.1: Recommended minimum follow-up schedule in a surveillance policy: stage I non-seminoma

Procedure	Year			
	1	2	3	4-5
Physical examination	4 times	4 times	4 times	Once/year
Tumour markers	4 times	4 times	4 times	Once/year
Plain radiography chest	Twice		Twice	
Abdominopelvic CT	Twice (at 3 and 12 months)		Once in year 2 (at 24 months), Once in year 3 (at 36 months)	

CT = computed tomography.

Table 8.2: Recommended minimum follow-up schedule after retroperitoneal lymphadenectomy or adjuvant chemotherapy: stage I non-seminoma

Procedure	Year				
	1	2	3	4-5	6-10
Physical examination	4 times	4 times	4 times	Once/year	Once/year
Tumour markers	4 times	4 times	4 times	Once/year	Once/year
Plain radiography chest	Twice	Twice	Twice		
Abdominopelvic CT	Once	Once	Once	Once/year	

CT = computed tomography.

Table 8.3: Recommended minimum follow-up schedule for post-orchietomy surveillance, radiotherapy or chemotherapy: stage I seminoma

Procedure	Year		
	1	2	3-5
Physical examination	3 times	3 times	Once/year
Tumour markers	3 times	3 times	Once/year
Plain radiography chest	Twice	Twice	
Abdominopelvic CT	Twice	Twice	at 36 and 60 months

CT = computed tomography.

Table 8.4: Recommended minimum follow-up schedule in metastatic NSGCT and seminoma

Procedure	Year			
	1	2	3-5	Thereafter
Physical examination	4 times	4 times	Twice/year	Once/year
Tumour markers	4 times	4 times	Twice/year	Once/year
Plain radiography chest	4 times	4 times	Twice/year	Once/year
Abdominopelvic CT [†]	Twice	Twice	Once/year	As indicated
Chest CT [‡]	Once/year	Once/year	Once/year	As indicated
Brain CT [§]	Once/year	Once/year	Once/year	As indicated

CT = computed tomography.

* An abdominal CT must be performed at least annually if teratoma is found in the retroperitoneum.

[†] If the post-chemotherapy evaluation in a seminoma patient shows any mass > 3 cm, the appropriate CT should be repeated 2 and 4 months later to ensure that the mass is continuing to regress. If available, FDG-PET/CT can be performed.

[‡] A chest CT is indicated if abnormality is detected on a plain radiography chest and after pulmonary resection.

[§] In patients with headaches, focal neurological findings, or any central nervous system symptoms.

2. METHODS

For the Germ-cell tumour Section, the literature has been assessed and updated throughout the document.

For the Testicular Stromal tumours a scoping search as of Jan 1st, 2009 until October 13th, 2014 has been carried out. No restrictions on data level were applied. The search identified 758 unique records, of which 18 references were included in the manuscript.

2.1 Review

This document was subjected to double-blind peer review prior to publication.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology

Testicular cancer represents 1% of male neoplasms and 5% of urological tumours, with 3-10 new cases occurring per 100,000 males/per year in Western society [2-5]. Its incidence has been increasing during the last decades especially in the industrialised countries [6-8]. Data from the Surveillance Epidemiology and End Results (SEER) program (1973 to 1998) show a continuing increased risk among Caucasian men in the USA only for seminoma [9].

At diagnosis, 1-2% of cases are bilateral and the predominant histology is germ cell tumour (90-95% of cases) [2]. Peak incidence is in the third decade of life for non-seminoma, and in the fourth decade for pure seminoma.

Testicular cancers (TC) show excellent cure rates based on their chemosensitivity especially to cisplatin-based chemotherapy [10], careful staging at diagnosis, adequate early treatment based on multidisciplinary approach and strict follow-up and salvage therapies. A decrease in the mean time of delay to diagnosis and treatment has been observed. Although early stages can be successfully treated in a non-reference centre, the relapse rate is higher [11]. In poor prognosis non-seminomatous germ cell tumours, overall survival (OS) within a clinical trial depends on the number of patients treated at the participating centre (worse if < 5 patients enrolled) [12]. In the same context, the frequency of post-chemotherapy residual tumour resection is associated with perioperative mortality and OS [13, 14].

Genetic changes have been described in patients with testicular cancer. A specific genetic marker (an isochromosome of the short arm of chromosome 12 - i(12p) - has been described in all histological types of germ cell tumours [15] and in testicular intraepithelial neoplasia (TIN). Alterations in the p53 locus have been identified in 66% of cases of testicular TIN [16]. A deregulation in the pluripotent program of foetal germ cells (identified by specific markers, M2A, C-KIT and OCT4/NANOG) is likely responsible for the development of TIN and germ cell neoplasia. There is overlap in the development to seminoma and embryonal carcinoma as shown by genome-wide expression analysis and detection of alpha-fetoprotein (AFP) mRNA in some atypical seminoma [17, 18].

Epidemiological risk factors for the development of testicular tumours are components of the testicular dysgenesis syndrome (i.e. cryptorchidism, hypospadias, decreased spermatogenesis evidenced by sub- or infertility) [19, 20], familial history of testicular tumours among first-grade relatives and the presence of a contralateral tumour or TIN [15, 19, 21-29]. Very tall men seem to have a higher risk of GCT (OR 3.35), while short stature is protective [30, 31], although further confirmation is needed.

3.2 Pathological classification

The recommended pathological classification (modified from the 2004 version of the World Health Organization [WHO] guidance) is shown below [32].

1. Germ cell tumours

- Intratubular germ cell neoplasia, unclassified type (IGCNU)
- Seminoma (including cases with syncytiotrophoblastic cells)
- Spermatocytic seminoma (mention if there is a sarcomatous component)
- Embryonal carcinoma

- Yolk sac tumour
- Choriocarcinoma
- Teratoma (mature, immature, with malignant component)
- Tumours with more than one histological type (specify percentage of individual components).

2. **Sex cord/gonadal stromal tumours**

- Leydig cell tumour
- Malignant Leydig cell tumour
- Sertoli cell tumour
 - lipid-rich variant
 - sclerosing
 - large cell calcifying
- Malignant Sertoli cell tumour
- Granulosa cell tumour
 - adult type
 - juvenile type
- Thecoma/fibroma group of tumours
- Other sex cord/gonadal stromal tumours
 - incompletely differentiated
 - mixed
- Tumours containing germ cell and sex cord/gonadal stromal (gonadoblastoma).

3. **Miscellaneous non-specific stromal tumours**

- Ovarian epithelial tumours
- Tumours of the collecting ducts and rete testis
- Tumours (benign and malignant) of non-specific stroma.

4. **STAGING AND CLASSIFICATION SYSTEMS**

4.1 **Diagnostic tools**

To determine the presence of macroscopic or occult metastatic disease, the half-life kinetics of serum tumour markers as well as the presence of nodal or visceral metastases need to be assessed.

Consequently, it is mandatory to assess:

- the post-orchietomy half-life kinetics of serum tumour markers;
- the status of retroperitoneal and supraclavicular lymph nodes, bone and liver;
- the presence or absence of mediastinal nodal involvement and lung metastases;
- the status of brain and bone in cases of suspicious symptoms or high-risk disease, e.g. poor IGCCCG risk group, high hCG and/or multiple pulmonary metastases.

The minimum mandatory tests are:

- serial blood sampling;
- abdominopelvic and chest computed tomography (CT).

4.2 **Serum tumour markers: post-orchietomy half-life kinetics**

The mean serum half-life of AFP and hCG is 5-7 days and 2-3 days, respectively [33]. Tumour markers need to be re-evaluated after orchietomy to determine half-life kinetics. Marker decline in patients with clinical stage I disease should be assessed until normalisation has occurred. Markers before the start of chemotherapy are important to classify the patient according to the International Germ Cell Cancer Collaborative Group (IGCCCG) risk classification [34]. The persistence of elevated serum tumour markers after orchietomy might indicate the presence of metastatic disease (macro- or microscopically), while the normalisation of marker levels after orchietomy does not rule out the presence of tumour metastases. During chemotherapy, the markers should decline; persistence has an adverse prognostic value [35, 36]. Slow marker decline in patients with “poor prognosis” during the first cycle of standard BEP chemotherapy can be used as an indication for early chemotherapy dose intensification [37].

4.3 **Retroperitoneal, mediastinal and supraclavicular lymph nodes and viscera**

Retroperitoneal and mediastinal lymph nodes are best assessed by CT. The supraclavicular nodes are best assessed by physical examination.

Abdominopelvic CT offers a sensitivity of 70-80% in determining the state of the retroperitoneal nodes. Its accuracy depends on the size and shape of the nodes; sensitivity and the negative predictive value increase using a 3 mm threshold to define metastatic nodes in the landing zones [38]. Those figures decrease slightly in stages I and II [39, 40], with a rate of understaging of 25-30% [41]. New generations of CT devices do not seem to improve the sensitivity.

Magnetic resonance imaging (MRI) produces similar results to CT in the detection of retroperitoneal nodal enlargement [42, 43]. Again, the main objections to its routine use are its high cost and limited availability. Nevertheless, MRI can be helpful when abdominopelvic CT or US are inconclusive [42], when CT is contraindicated because of allergy to contrast media, or when the physician or the patient are concerned about radiation dose. MRI is an optional test, and there are currently no indications for its systematic use in the staging of testicular cancer.

A chest CT is the most sensitive way to evaluate the thorax and mediastinal nodes. This exploration has to be recommended in all patients with testicular cancer as up to 10% of cases can present with small subpleural nodes that are not visible radiologically [44]. A CT has high sensitivity, but low specificity [42].

There is no evidence to support the use of fluorodeoxyglucose-PET (FDG-PET) in the staging of testis cancer [45-48]. It is recommended in the follow-up of patients with seminoma with any residual mass at least 6 weeks after the end of the last cycle of chemotherapy in order to decide on watchful waiting or active treatment [47-51].

Fluorodeoxyglucose-PET, however, is not recommended in the re-staging of patients with non-seminomatous tumours after chemotherapy [52, 53].

Other examinations, such as brain or spinal CT, bone scan or liver ultrasound, should be performed if there is suspicion of metastases to these organs. A CT or MRI of the skull is advisable in patients with NSGCT and multiple lung metastases and poor prognosis IGCCG risk group (e.g. high beta-hCG values). Table 4.1 shows the recommended tests at staging.

Table 4.1: Recommended tests for staging at diagnosis

Test	Recommendation	GR
Serum tumour markers	Alpha-fetoprotein hCG LDH	A
Abdominopelvic CT	All patients	A
Chest CT	All patients	A
Testis ultrasound (bilateral)	All patients	A
Bone scan or MRI columna	In case of symptoms	
Brain scan (CT/MRI)	In case of symptoms and patients with metastatic disease with multiple lung metastases and/or high beta-hCG values.	
Further investigations		
Fertility investigations: Total testosterone LH FSH Semen analysis		B
Sperm banking	Should be offered	A

hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase; CT = computed tomography; LH = luteinising hormone; FSH = follicle-stimulating hormone.

4.4 Staging and prognostic classifications

The staging system recommended in these guidelines is the 2009 TNM of the International Union Against Cancer (UICC) (Table 4.2) [54]. This includes:

- determination of the anatomical extent of disease;
- assessment of serum tumour markers, including nadir values of hCG, AFP and LDH after orchiectomy (S category);
- definition of regional nodes;
- N-category modifications related to node size.

Table 4.2: TNM classification for testicular cancer (UICC, 2009, 7th edn. [54])

pT		Primary tumour ¹		
	pTX	Primary tumour cannot be assessed (see note 1)		
	pT0	No evidence of primary tumour (e.g. histological scar in testis)		
	pTis	Intratubular germ cell neoplasia (testicular intraepithelial neoplasia)		
	pT1	Tumour limited to testis and epididymis without vascular/lymphatic invasion: tumour may invade tunica albuginea but not tunica vaginalis		
	pT2	Tumour limited to testis and epididymis with vascular/lymphatic invasion, or tumour extending through tunica albuginea with involvement of tunica vaginalis		
	pT3	Tumour invades spermatic cord with or without vascular/lymphatic invasion		
	pT4	Tumour invades scrotum with or without vascular/lymphatic invasion		
N		Regional lymph nodes clinical		
	NX	Regional lymph nodes cannot be assessed		
	N0	No regional lymph node metastasis		
	N1	Metastasis with a lymph node mass 2 cm or less in greatest dimension or multiple lymph nodes, none more than 2 cm in greatest dimension		
	N2	Metastasis with a lymph node mass more than 2 cm but not more than 5 cm in greatest dimension, or multiple lymph nodes, any one mass more than 2 cm but not more than 5 cm in greatest dimension		
	N3	Metastasis with a lymph node mass more than 5 cm in greatest dimension		
pN		Pathological		
	pNX	Regional lymph nodes cannot be assessed		
	pN0	No regional lymph node metastasis		
	pN1	Metastasis with a lymph node mass 2 cm or less in greatest dimension and 5 or fewer positive nodes, none more than 2 cm in greatest dimension		
	pN2	Metastasis with a lymph node mass more than 2 cm but not more than 5 cm in greatest dimension; or more than 5 nodes positive, none more than 5 cm; or evidence of extranodal extension of tumour		
	pN3	Metastasis with a lymph node mass more than 5 cm in greatest dimension		
M		Distant metastasis		
	MX	Distant metastasis cannot be assessed		
	M0	No distant metastasis		
	M1	Distant metastasis		
		M1a Non-regional lymph node(s) or lung		
		M1b Other sites		
S		Serum tumour markers		
	SX	Serum marker studies not available or not performed		
	S0	Serum marker study levels within normal limits		
		LDH (U/l)	hCG (mIU/mL)	AFP (ng/mL)
	S1	< 1.5 x N and	< 5,000 and	< 1,000
	S2	1.5-10 x N or	5,000-50,000 or	1,000-10,000
	S3	> 10 x N or	> 50,000 or	> 10,000

N indicates the upper limit of normal for the LDH assay.

LDH = lactate dehydrogenase; hCG = human chorionic gonadotrophin; AFP = alpha-fetoprotein.

¹Except for pTis and pT4, where radical orchidectomy is not always necessary for classification purposes, the extent of the primary tumour is classified after radical orchidectomy; see pT. In other circumstances, TX is used if no radical orchidectomy has been performed.

According to the 2009 TNM classification, stage I testicular cancer includes the following substages:

Stage grouping

Stage 0	pTis	N0	M0	S0,SX
Stage I	pT1-T4	N0	M0	SX
Stage IA	pT1	N0	M0	S0
Stage IB	pT2 - pT4	N0	M0	S0
Stage IS	Any patient/TX	N0	M0	S1-3
Stage II	Any patient/TX	N1-N3	M0	SX
Stage IIA	Any patient/TX	N1	M0	S0
	Any patient/TX	N1	M0	S1
Stage IIB	Any patient/TX	N2	M0	S0
	Any patient/TX	N2	M0	S1
Stage IIC	Any patient/TX	N3	M0	S0
	Any patient/TX	N3	M0	S1
Stage III	Any patient/TX	Any N	M1a	SX
Stage IIIA	Any patient/TX	Any N	M1a	S0
	Any patient/TX	Any N	M1a	S1
Stage IIIB	Any patient/TX	N1-N3	M0	S2
	Any patient/TX	Any N	M1a	S2
Stage IIIC	Any patient/TX	N1-N3	M0	S3
	Any patient/TX	Any N	M1a	S3
	Any patient/TX	Any N	M1b	Any S

- Stage IA patients have primary tumours limited to the testis and epididymis, with no evidence of microscopic vascular or lymphatic invasion by tumour cells on microscopy, no sign of metastases on clinical examination or imaging, and post-orchietomy serum tumour marker levels within normal limits. Marker decline in patients with clinical stage I disease should be assessed until normalisation.
- Stage IB patients have a more locally invasive primary tumour, but no sign of metastatic disease.
- Stage IS patients have persistently elevated (and usually increasing) serum tumour marker levels after orchietomy, indicating subclinical metastatic disease (or possibly a second germ cell tumour in the remaining testis).

In large population-based patient series, 75-80% of seminoma patients, and about 55% of patients with NSGCT cancer have stage I disease at diagnosis [55-57]. True stage IS (persistently elevated or increasing serum marker levels after orchietomy) is found in about 5% of non-seminoma patients.

In 1997, the IGCCCG defined a prognostic factor-based staging system for metastatic testis tumour based on identification of some clinical independent adverse factors. This staging system has been incorporated into the TNM Classification and uses histology, location of the primary tumour, location of metastases and prechemotherapy marker levels in serum as prognostic factors to categorise patients into 'good', 'intermediate' or 'poor' prognosis (Table 4.3) [34].

Table 4.3: Prognostic-based staging system for metastatic germ cell cancer (International Germ Cell Cancer Collaborative Group)*

Good-prognosis group	
Non-seminoma (56% of cases) 5-year PFS 89% 5-year survival 92%	<i>All of the following criteria:</i> <ul style="list-style-type: none"> • Testis/retroperitoneal primary • No non-pulmonary visceral metastases • AFP < 1,000 ng/mL • hCG < 5,000 IU/L (1,000 ng/mL) • LDH < 1.5 x ULN
Seminoma (90% of cases) 5-year PFS 82% 5-year survival 86%	<i>All of the following criteria:</i> <ul style="list-style-type: none"> • Any primary site • No non-pulmonary visceral metastases • Normal AFP • Any hCG • Any LDH
Intermediate prognosis group	
Non-seminoma (28% of cases) 5-year PFS 75% 5-year survival 80%	<ul style="list-style-type: none"> • Testis/retroperitoneal primary • No non-pulmonary visceral metastases • AFP 1,000 - 10,000 ng/mL or • hCG 5,000 - 50,000 IU/L or • LDH 1.5 - 10 x ULN
Seminoma (10% of cases) 5-year PFS 67% 5-year survival 72%	<i>All of the following criteria:</i> <ul style="list-style-type: none"> • Any primary site • Non-pulmonary visceral metastases • Normal AFP • Any hCG • Any LDH
Poor prognosis group	
Non-seminoma (16% of cases) 5-year PFS 41% 5-year survival 48%	<i>Any of the following criteria:</i> <ul style="list-style-type: none"> • Mediastinal primary • Non-pulmonary visceral metastases • AFP > 10,000 ng/mL or • hCG > 50,000 IU/L (10,000 ng/mL) or • LDH > 10 x ULN
Seminoma	No patients classified as poor prognosis

*Pre-chemotherapy serum tumour markers should be assessed immediately prior to the administration of chemotherapy (same day).

PFS = progression-free survival; AFP = alpha-fetoprotein; hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase.

5. DIAGNOSTIC EVALUATION

5.1 Clinical examination

TC presents as a painless, unilateral testicular scrotal mass, as a casual US finding or revealed by a scrotal trauma [58]. Scrotal pain may be the first symptom in 20% of cases and it is present in up to 27% of patients with testicular cancer [58, 59]. Gynaecomastia appears in 7% of cases (more common in non-seminomatous tumours). Back and flank pain due to metastasis is present in about 11% of cases [59].

Diagnosis is delayed in around 10% of cases of testicular tumour that mimic orchioepididymitis [59], physical examination reveals the features of the mass and must always be carried out together with a general examination to find possible (supraclavicular) distant metastases, a palpable abdominal mass or gynaecomastia. Ultrasound (US) must be performed in any doubtful case. A correct diagnosis must be established in all patients with an intrascrotal mass [60].

5.2 Imaging of the testis

Currently, US serves to confirm the presence of a testicular mass and to explore the contralateral testis. Its sensitivity is almost 100%, and it has an important role in determining whether a mass is intra- or extratesticular [61]. Ultrasound is an inexpensive test and should be performed even in the presence of clinically evident testicular tumour [62].

US of the testis should be performed in young men with retroperitoneal or visceral masses and/or elevated serum human chorionic gonadotrophin (hCG) or alpha-fetoprotein (AFP) and/or consulting for fertility problems and without a palpable testicular mass [63-65].

Magnetic resonance imaging (MRI) of scrotum offers higher sensitivity and specificity than US in the diagnosis of TC, but its high cost does not justify its routine use for diagnosis [61, 66].

5.3 Serum tumour markers at diagnosis

Serum tumour markers are prognostic factors and contribute to diagnosis and staging [67]. The following markers should be determined before, and 5-7 days after, orchiectomy:

- AFP (produced by yolk sac cells);
- hCG (expression of trophoblasts);
- LDH (lactate dehydrogenase).

Tumour markers are of value for diagnosis (before orchiectomy) as well as for prognosis (after orchiectomy). They are increased in approximately every second patient with testicular cancer [5, 58]. AFP and hCG are increased in 50-70% and in 40-60% of patients with non-seminomatous germ cell tumour (NSGCT), respectively. About 90% of NSGCT present with a rise in one or two of the markers. Up to 30% of seminomas can present or develop an elevated hCG level during the course of the disease [33, 68].

LDH is a less specific marker, its concentration being proportional to tumour volume. Its level may be elevated in 80% of patients with advanced testicular cancer [33]. Of note, negative marker levels do not exclude the diagnosis of a germ cell tumour. Placental alkaline phosphatase (PLAP), is an optional marker in monitoring patients with pure seminoma, but not recommended in smokers [69].

Cytogenetic and molecular markers are available in specific centres, but at present only contribute to research.

5.4 Inguinal exploration and orchiectomy

Every patient with a suspected testicular mass must undergo inguinal exploration with exteriorisation of the testis within its tunics. Orchiectomy with division of the spermatic cord at the internal inguinal ring must be performed if a malignant tumour is found. If the diagnosis is not clear, a testicular biopsy (and enucleation of the intraparenchymal tumour) is taken for frozen (fresh tissue) section histological examination.

In cases of life threatening disseminated disease, lifesaving chemotherapy should be given up-front, especially when the clinical picture is very likely testicular cancer and/or tumour markers are increased. Orchiectomy may be delayed until clinical stabilisation occurs or in combination with resection of residual lesions.

5.5 Organ-sparing surgery

Although organ-sparing surgery is not indicated in the presence of non-tumoural contralateral testis, it can be attempted in special cases with all the necessary precautions.

In synchronous bilateral testicular tumours, metachronous contralateral tumours, or in a tumour in a solitary testis with normal pre-operative testosterone levels, organ preserving surgery can be performed when tumour volume is less than 30% of the testicular volume and surgical rules are respected. In those cases, the rate of associated TIN is high (at least up to 82%) (see Section 5.7.)

5.6 Pathological examination of the testis

Mandatory pathological requirements:

- Macroscopic features: side, testis size, maximum tumour size, and macroscopic features of the epididymis, spermatic cord, and tunica vaginalis.
- Sampling: a 1 cm² section for every centimetre of maximum tumour diameter, including normal macroscopic parenchyma (if present), albuginea and epididymis, with selection of suspected areas. At least one proximal and one distal section of spermatic cord plus any suspected area.
- Microscopic features and diagnosis: histological type (specify individual components and estimate amount as percentage) according to WHO 2004 [32]:
 - presence or absence of peri-tumoural venous and/or lymphatic invasion;
 - presence or absence of albuginea, tunica vaginalis, rete testis, epididymis or spermatic cord invasion;

- presence or absence of (TIN/ITGCN [intratubular germ cell neoplasia]) in non-tumour parenchyma
Intratubular germ cell neoplasia.
- pT category according to Tumour Node Metastasis (TNM) 2009 [54].
- Immunohistochemical studies: in seminoma and mixed germ cell tumour, AFP and hCG.

Advisable immunohistochemical markers, in cases of doubt, are:

- in seminoma: cytokeratins (CAM 5.2), PLAP, c-kit;
- in intratubular germ cell neoplasia: PLAP, c-kit;
- other advisable markers: chromogranin A (Cg A), Ki-67 (MIB-1).

5.7 Diagnosis and treatment of testicular intraepithelial neoplasia (TIN)

Contralateral biopsy has been advocated to rule out the presence of TIN [70]. Although routine policy in some countries, the low incidence of TIN and contralateral metachronous testicular tumours (up to 9% and approximately 2.5%, respectively) [71, 72], the morbidity of TIN treatment, and the fact that most of metachronous tumours are at a low stage at presentation make it controversial to recommend a systematic contralateral biopsy in all patients [73-75].

It is still difficult to reach a consensus on whether the existence of contralateral TIN must be identified in all cases. However, biopsy of the contralateral testis should be offered to patients at high risk for contralateral TIN, i.e. testicular volume < 12 mL, a history of cryptorchidism or poor spermatogenesis (Johnson Score 1-3). A contralateral biopsy is not necessary in patients older than 40 years without risk factors [38, 57, 76-79]. A double biopsy increases sensitivity [77]. Patients should be informed that a testicular tumour may arise in spite of a negative biopsy [80].

Once TIN is diagnosed, local radiotherapy (16-20 Gy in fractions of 2 Gy) is the treatment of choice in the case of a solitary testis. Testicular radiotherapy in a solitary testis will result in infertility and increased long-term risk of Leydig cell insufficiency [39, 73, 81, 82]. Fertile patients who wish to father children may delay radiation therapy and be followed by regular testicular US [77].

If TIN is diagnosed and the contralateral testis is healthy, the options for management are orchiectomy or close observation (with a 5-year risk of developing TC of 50%) [83].

5.8 Screening

There are no surveys proving the advantages of screening programmes, but it has been demonstrated that stage and prognosis are directly related to early diagnosis. In the presence of clinical risk factors, self-physical examination by the affected individual is advisable.

5.9 Guidelines for the diagnosis and staging of testicular cancer

	GR
Testicular US is a mandatory assessment.	A
Biopsy of the contralateral testis should be offered (and its consequences discussed) to patients at high risk for contralateral TIN.	A
Orchiectomy and pathological examination of the testis are necessary to confirm the diagnosis and to define the local extension (pT category). In a life-threatening situation due to extensive metastasis, chemotherapy must be started before orchiectomy.	A
Serum determination of tumour markers (AFP, hCG, and LDH) must be performed both before and 5-7 days after orchiectomy for staging and prognostic reasons.	A
The state of the retroperitoneal, mediastinal and supraclavicular nodes and viscera must be assessed in testicular cancer.	A

AFP = alpha-fetoprotein; hCG = human chorionic gonadotrophin; LDH = lactate dehydrogenase; TIN = testicular intraepithelial neoplasia.

6. PROGNOSIS

6.1 Risk factors for metastatic relapse in stage I GCT

Retrospectively, for seminoma stage I, tumour size (> 4 cm) and invasion of the rete testis have been identified as predictors for relapse in a pooled analysis [84]. However, these risk factors have not been validated in a prospective setting except that the absence of both factors indicated a low recurrence rate (6%) [85].

For non-seminoma stage I, vascular invasion of the primary tumour in blood or lymphatic vessels is the most important predictor of occult metastatic disease. The proliferation rate, as well as the percentage of embryonal carcinoma, are additional predictors that improve upon the positive and negative predictive value of vascular invasion [86, 87]. Whether the absence of teratoma (as qualitative data, as opposed to the more subjective assessment of percentage of embryonal carcinoma) can independently complement vascular invasion as a predictive factor of relapse requires validation [88].

The significant prognostic pathological risk factors for stage I testicular cancer are listed in Table 6.1.

Table 6.1: Risk factors for occult metastatic disease in stage I testicular cancer

	For seminoma	For non-seminoma
Pathological (for stage I)		
Histopathological type	<ul style="list-style-type: none">• Tumour size (> 4 cm)• Invasion of the rete testis	<ul style="list-style-type: none">• Vascular/lymphatic in or peri-tumoural invasion• Proliferation rate > 70%• Percentage of embryonal carcinoma > 50%

7. DISEASE MANAGEMENT

7.1 Impact on fertility and fertility-associated issues

Sperm abnormalities are frequently found in patients with testis tumours. Furthermore, chemotherapy and radiation treatment can also impair fertility. In patients in the reproductive age group, pre-treatment fertility assessment (testosterone, luteinising hormone [LH] and follicle stimulating hormone [FSH] levels) should be performed, and semen analysis and cryopreservation should be offered. If cryopreservation is desired, it should preferably be performed before orchiectomy, but in any case prior to chemotherapy treatment [81, 89-95]. In cases of bilateral orchiectomy or low testosterone levels after treatment of TIN, life-long testosterone supplementation is necessary [96]. Patients with unilateral or bilateral orchiectomy should be offered a testicular prosthesis [97]. For more detailed information, the reader is referred to the EAU Male Infertility Guidelines [98].

7.2 Stage I Germ cell tumours

7.2.1 Stage I seminoma

After modern staging procedures, about 15-20% of stage I seminoma patients have subclinical metastatic disease, usually in the retroperitoneum, and will relapse after orchiectomy alone.

The decision regarding adjuvant treatment should always be based on a thorough discussion with the patient, taking into account the described advantages and disadvantages, as well as the individual situation of the patient.

7.2.1.1 Surveillance

Several prospective non-randomised surveillance studies have been conducted during the past decade, the largest study from Canada with > 1,500 patients [99]. Previous analyses from four studies showed an actuarial 5-year relapse-free rate of 82.3%. The Princess Margaret Hospital series (n = 1559) showed an overall relapse rate in unselected patients of 16.8%. The actuarial relapse rate is in the order of 15-20% at 5 years, and most of the relapses are first detected in infra-diaphragmatic lymph nodes [100].

In patients with low risk (tumour size ≤ 4 cm and no rete testis invasion), the recurrence under surveillance is as low as 6% [101]. Chemotherapy, according to the IGCCCG classification, is a possible treatment for seminoma relapse under surveillance. However, 70% of patients with relapse are suitable for treatment with radiotherapy alone because of small volume disease at the time of recurrence. Patients who relapse after salvage radiotherapy can be effectively treated with chemotherapy [102]. The combination of

carboplatin chemotherapy and modern radiotherapy for treatment of low stage seminoma relapse (IIA/IIB) is under investigation.

The overall cancer-specific survival rate reported under surveillance performed by experienced centres is 97-100% for seminoma stage I [100, 102]. The main drawback of surveillance is the need for more intensive follow-up, especially with repeated imaging examinations of the retroperitoneal lymph nodes.

7.2.1.2 Adjuvant chemotherapy

A joint trial by the Medical Research Council (MRC) and the European Organisation for Research and Treatment of Cancer (EORTC) (MRC TE 19 trial), which compared one cycle of carboplatin (area under curve [AUC] 7) with adjuvant radiotherapy, did not show a significant difference with regard to recurrence rate, time to recurrence and survival after a median follow-up of 4 years [103-105]. Therefore, adjuvant carboplatin therapy using a dosage of one course of AUC 7 is an alternative to radiotherapy or surveillance in stage I seminoma [100, 103-105]. Two courses of adjuvant carboplatin seem to further reduce the relapse rate to the order of 1-3% [85, 106], but additional experience and long-term observation are needed.

7.2.1.3 Adjuvant radiotherapy and risk-adapted treatment

Seminoma cells are extremely radiosensitive. Adjuvant radiotherapy to a para-aortic (PA) field or to a paraaortic and ipsilateral field (para-aortic and ipsilateral iliac nodes), with moderate doses (total 20-24 Gy), will reduce the relapse rate to 1-3% [107-110]. Adjuvant irradiation of supradiaphragmatic lymph nodes is not indicated in seminoma stage I.

With regard to the irradiation dose, a large MRC randomised trial of 20 Gy versus 30 Gy PA radiation in stage I seminoma showed equivalence for both doses in terms of recurrence rates [108]. The rate of severe radiation-induced long-term toxicity is less than 2%. Moderate chronic gastrointestinal (GI) side-effects are seen in about 5% of patients, and moderate acute GI toxicity in about 60% [107]. The main concern surrounding adjuvant radiotherapy is the increased risk of radiation-induced second non-germ cell malignancies [111-116]. Therefore, in young patients (< 40 yrs) adjuvant radiotherapy should no longer be used.

A scrotal shield should be considered during adjuvant radiotherapy in order to prevent scattered radiation toxicity in the contralateral testis [114].

7.2.1.4 Risk-adapted treatment

Using tumour size > 4 cm and rete testis invasion, patients with seminoma stage I may be subdivided into a low-and high-risk group of occult metastatic disease. Patients with and without both risk factors have a risk of occult disease of 32% and 12%, respectively. These risk factors were introduced by an analysis of retrospective trials [84]. A prospective trial based on these risk factors (no risk factors: surveillance; both risk factors: two courses of carboplatin AUC 7) showed the feasibility of a risk-adapted approach. Early data with limited follow-up indicate that patients without either risk factor have a very low risk of 6.0% - 14.8% of relapse at 5 years. Patients in the high-risk group treated with carboplatin experienced a 1.4% - 3.2% relapse rate at mean follow up of 34 months [101, 117].

7.2.1.5 Retroperitoneal lymph node dissection (RPLND)

In a prospective, non-randomised study comparing radiotherapy and RPLND in stage I seminoma, there was a trend towards a higher incidence of retroperitoneal relapses (9.5%) after RPLND as primary treatment. Therefore, this policy should not be recommended in stage I seminoma [115].

7.2.2 Guidelines for the treatment of seminoma stage I

	GR
Surveillance is a recommended management option (if facilities available and patient compliant).	A*
Carboplatin-based chemotherapy (one course at AUC 7) is recommended.	B
Adjuvant treatment is not recommended for patients at very low risk.	A
Radiotherapy is not recommended as adjuvant treatment.	A

*Upgraded following panel consensus.

7.3 NSGCT clinical stage I

Up to 30% of NSGCT patients with clinical stage I (CS1) disease have subclinical metastases and will relapse if surveillance alone is applied after orchiectomy. The decision regarding adjuvant treatment should always be based on a thorough discussion with the patient, taking into account the described advantages and

disadvantages, as well as the individual situation of the patient.

7.3.1 **Surveillance**

Improvements in clinical staging and follow-up methods, and the availability of effective salvage treatment with cisplatin-based chemotherapy and post-chemotherapy surgery, have led to studies of only close surveillance after orchiectomy in CS1 NSGCT patients. The largest reports of the surveillance strategy indicate a cumulative relapse rate of about 30%, with 80% of relapses occurring during the first 12 months of follow-up, 12% during the second year and 6% during the third year, decreasing to 1% during the fourth and fifth years, and occasionally even later [118-122]. About 35% of relapsing patients have normal levels of serum tumour markers at relapse. About 60% of relapses are in the retroperitoneum. Despite very close follow-up, 11% of relapsing patients presented with large-volume recurrent disease.

The somewhat lower relapse rates reported from surveillance studies compared with some series of patients staged by RPLND [123] can be explained by the fact that some patients (presumably at higher risk) are excluded once surveillance is advised. Based on the overall cancer-specific survival data, surveillance within an experienced surveillance programme can safely be offered to patients with non-risk stratified clinical stage I non-seminoma as long as they are compliant and informed about the expected recurrence rate as well as the salvage treatment [124-126].

7.3.2 **Adjuvant chemotherapy**

Patients with CS1 NSGCT have a 14-48% risk of recurrence within 2 years after orchiectomy. Adjuvant chemotherapy with two courses of cisplatin, etoposide, and bleomycin (BEP) was introduced in 1996 by a prospective MRC trial [127]. Subsequently, adjuvant chemotherapy was mainly given in patients with high risk (vascular invasion present) [127-132]. In these series, involving more than 200 patients, some with a median follow-up of nearly 7.9 years [127], a relapse rate of only 2.7% was reported, with very little long-term toxicity. Two cycles of cisplatin-based adjuvant chemotherapy do not seem to adversely affect fertility or sexual activity [133]. However, the very-long term (> 20 years) side effects of adjuvant chemotherapy in this setting are currently unknown, especially the long-term cardio-vascular effects of chemotherapy [134]. This should be taken in consideration for decision-making.

In 2008, the German Testicular Study Group reported a randomised trial of nerve-sparing RPLND or one course of BEP as adjuvant treatment in CS 1 NSGCT without risk-adaption. Adjuvant chemotherapy significantly increased the 2-year recurrence-free survival to 99.41% (confidence interval (CI): 95.87%, 99.92%) as opposed to surgery, which had a 2-year recurrence-free survival of 92.37% (CI: 87.21%, 95.50%). The difference was 7.04%, CI: 2.52%, 11.56% and, therefore, the main endpoint of the trial was reached. The hazard ratio to experience a tumour recurrence with surgery as opposed to chemotherapy was 7.937, CI: 1.808, 34.48. Of 174 patients having received one course of BEP, 43% had high risk features (> pT1) [135].

In a community-based prospective study, SWENOTECA recommended one course of BEP in LVI+ patients, while patients with LVI- chose between surveillance and BEP x 1 [136]. The relapse-rate of the 490 patients who received BEP x 1 at 5 years was 3.2% for patients with LVI and 1.6% for patients without LVI. After a median follow-up of 8.1 years the relapse rate was 2.3%, 3.4% and 1.3% for all, LVI+, and LVI-, respectively [137]. These numbers imply that > 90% of relapses were prevented by adjuvant chemotherapy and, importantly, no relapses were observed later than 3.3 years. Reduction from two to one cycle of BEP improves the risk-benefit ratio of adjuvant chemotherapy considerably.

In addition, it is important to be aware of slow-growing retroperitoneal teratomas after primary chemotherapy [138]. Until now, only a limited number of patients with long-term follow-up and toxicity data are reported so far [139].

The results of cost analyses comparing surveillance, RPLND and primary chemotherapy show different results among the reported studies, possibly because of differences in intensity and costs related to follow-up procedures [140]. With a low frequency of follow-up CTs (a surveillance strategy which has been proven to be effective in non-seminoma CS1), the costs of follow-up can be considerably reduced [141].

7.3.3 **Risk-adapted treatment**

Risk-adapted treatment is an alternative to the strategy of surveillance for all patients with CS 1 NSGCT. Risk-adapted treatment is based on the risk factor, vascular invasion. Stratifying patients with CS1 NSGCT according to their presumed risk of relapse is a rational option, as several studies have reported similar survival rates and a final cure rate close to 100% with all available treatment options using the risk-stratifying approach [127-132, 136, 137, 142-145].

If the risk-adapted policy is applied, patients with vascular invasion are recommended to undergo adjuvant chemotherapy and patients with absent vascular invasion are recommended a surveillance strategy. In the past, two cycles of BEP have been recommended for adjuvant treatment. In view of the low rates of recurrence (2-3%) and equivalent cancer-specific survival rates including salvage strategies in large prospective trials with sufficient follow-up, one cycle of BEP is recommended as adjuvant chemotherapy in patients with vascular invasion.

In cases of relapse after BEP x 1, three courses of BEP are recommended. However, there is not a large body of evidence to support one specific salvage regimen.

7.3.4 **Retroperitoneal lymph node dissection**

In view of the high cancer-specific survival rates of surveillance with salvage treatment in cases of relapse and the low relapse rates if adjuvant chemotherapy is chosen, the role of primary diagnostic retroperitoneal lymph node dissection has diminished. The randomised phase III trial of the German Testicular Cancer Study group compared RPLND to BEP x 1 as adjuvant treatment to show a more than expected difference of 7% in favour of chemotherapy. One course of BEP showed a significantly lower recurrence rate as compared to surgery [135].

If RPLND is performed in a multicentre setting, a higher rate of “in-field” recurrences and a higher rate of complications was reported [135, 146]. Thus, nerve-sparing RPLND - if indicated - should be performed by an experienced surgeon in specialised centres.

About 18-30% of patients are found to have retroperitoneal lymph node metastases on RPLND, corresponding to pathological stage II (PS2) disease [146-149]. If no retroperitoneal metastases are found at RPLND (PS1), approximately 10% of the PS1 patients relapse at distant sites [87, 124, 149, 150]. If metastases are present and not treated with adjuvant chemotherapy, recurrence will be found in 31% in patients [149].

The presence of vascular invasion, predominant embryonal carcinoma, pT category as well as a high number of and extranodal extension in metastatic nodes may be associated with an increased risk of recurrence in PS2 cases without adjuvant chemotherapy. Nonetheless, the clinical significance of these further parameters remains poor and not advisable in clinical practice [149, 151].

The follow-up after RPLND is simpler and less costly than that carried out during post-orchietomy surveillance because of the reduced need for abdominal CT scans [152]. If there is an indication to perform a staging RPLND, a laparoscopic or robot-assisted RPLND is feasible in expert hands. This minimal-invasive approach cannot be recommended as the standard approach outside of a specialised laparoscopic centre [153, 154].

7.3.5 **Guidelines for the treatment of NSGCT stage I**

	LE	GR
Patients with CS 1 NSGCT should be informed about all adjuvant treatment options after orchiectomy (surveillance, adjuvant chemotherapy, and RPLND) including treatment-specific recurrence rates as well as acute and long-term side effects.	2a	A*
Surveillance or risk-adapted treatment based on vascular invasion (see below) are recommended treatment options.	2a	A*
If patients are not willing to undergo the surveillance strategy, one course of BEP as adjuvant treatment has proven to be superior to RPLND in terms of recurrence rate in a community based study.	1b	A*
Salvage treatment of patients with recurrence during surveillance consists of three or four courses of BEP chemotherapy according to IGCCCG classification followed by post-chemotherapy retroperitoneal lymph node dissection if necessary.	2a	A

7.3.6 Risk-adapted treatment for CS1 based on vascular invasion

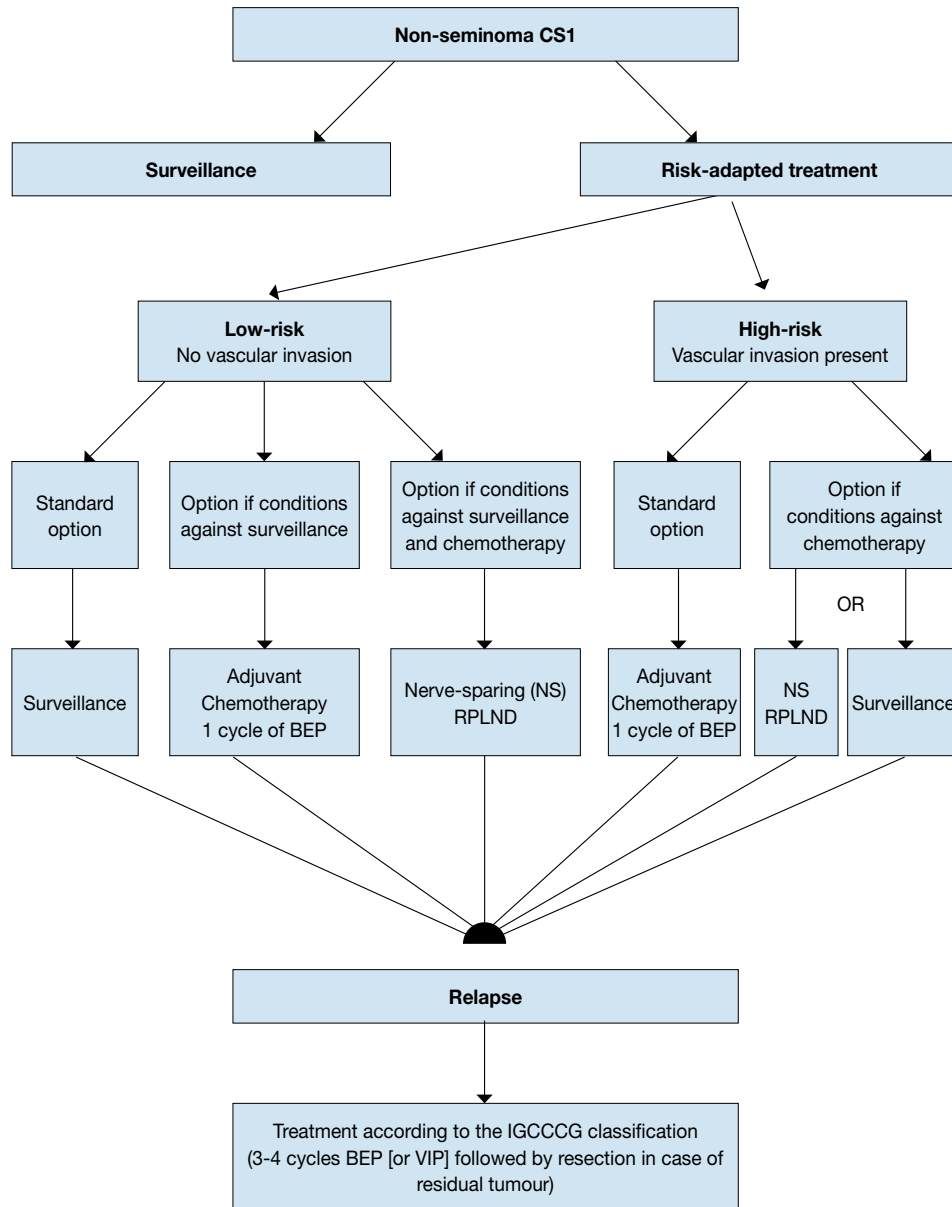

CS1A (pT1, no vascular invasion): low risk	LE	GR
Surveillance is recommended if the patient is willing and able to comply.	2a	A
In low-risk patients not willing (or suitable) to undergo surveillance, adjuvant chemotherapy with one course of BEP is recommended.	2a	A*
CS1B (pT2-pT4): high risk		
Primary chemotherapy with one course of BEP is recommended.	2a	A*
Patients should be informed about the advantages and disadvantages of two courses of BEP.		
Surveillance or nerve-sparing RPLND in high-risk patients remain options for those not willing to undergo adjuvant chemotherapy. If pathological stage II is revealed at RPLND, further chemotherapy as well as observation should be discussed with each patient.		A*

*Upgraded following panel consensus.

BEP = cisplatin, etoposide, bleomycin; RPLND = retroperitoneal lymph node dissection.

Figure 1 provides a treatment algorithm for patients with NSGCT stage I.

Figure 1: Risk-adapted treatment in patients with clinical stage 1 non-seminoma NSGCT CS1*

*All treatment options will need discussing with individual patients, to allow for them to make an informed decision as to their further care.

BEP = cisplatin, etoposide, bleomycin; CS = clinical stage; IGCCCG = International Germ Cell Cancer Collaborative Group; RLND = retroperitoneal lymph node dissection; VIP = etoposide, cisplatin, ifosfamide.

7.4 Metastatic germ cell tumours

The first-line treatment of metastatic germ cell tumours depends on:

- the histology of the primary tumour;
- prognostic groups as defined by the IGCCCG based on 5,202 non-seminoma and 660 seminoma cases (Table 4.3) [34].

In relapsed patients a new prognostic score has been developed including response to first-line therapy which can be used to estimate patient outcome following salvage chemotherapy.

7.4.1. **CS1S with (persistently) elevated serum tumour markers**

Serum tumour markers should be followed closely until levels fall into the reference values according to the expected half-life values for AFP and hCG. If the marker level increases after orchiectomy, the patient has residual disease. If RPLND is performed, up to 87% of these patients have pathologically documented nodes in the retroperitoneum [156]. An ultrasound examination of the contralateral testicle must be performed, if this was not done initially.

The treatment of true CS1S patients is still controversial. They may be treated with three courses of BEP chemotherapy and with follow-up as for CS1B patients (high risk, see below) after primary chemotherapy [157], or by RPLND [141].

7.4.2 **Metastatic disease (stage IIA/B)**

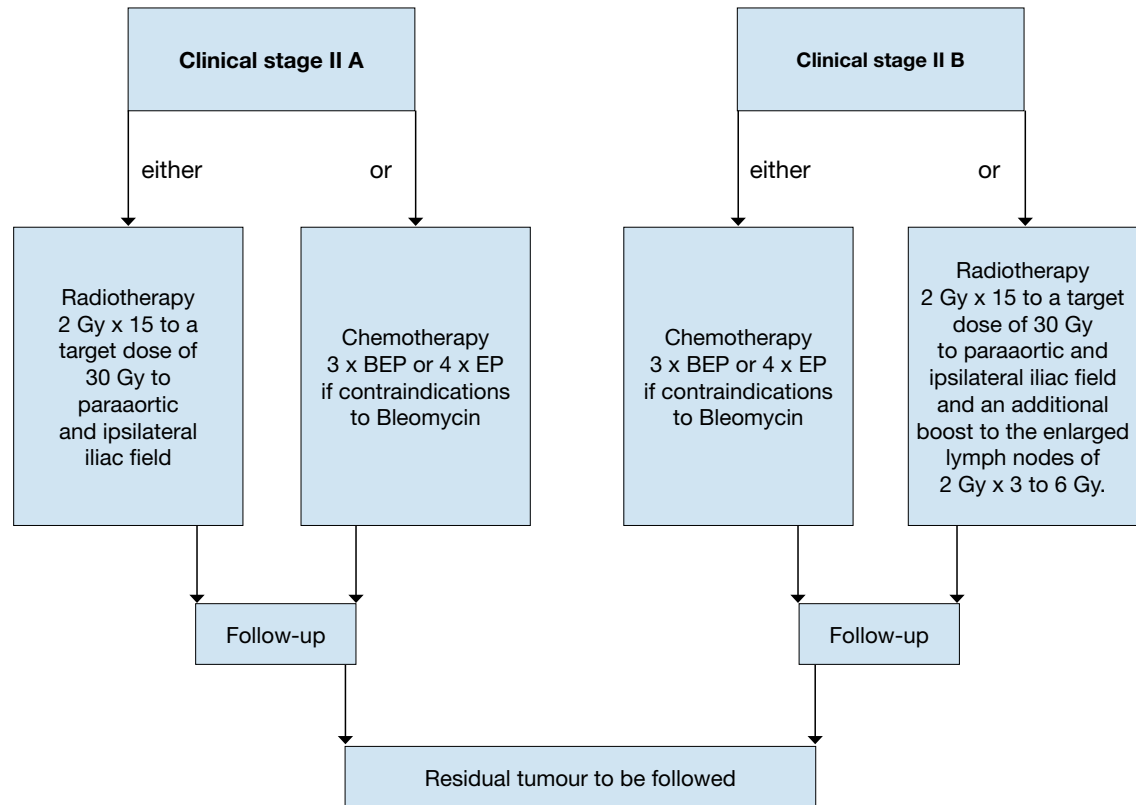

7.4.2.1 *Stage IIA/B seminoma*

Slightly enlarged retroperitoneal lymph nodes < 2 cm in patients without elevated tumour markers offer a diagnostic problem. These lymph nodes may be benign or, on the other hand, represent metastases. An observation period of 8 weeks with a second staging is recommended unless a biopsy verifies metastatic disease. Treatment should not be initiated unless metastatic disease is unequivocal, (e.g. growth or positive biopsy).

So far, the standard treatment for stage IIA/B seminoma has been radiotherapy with reported relapse rates of 9-24% [158-160]. Accumulating data on long-term morbidity, such as increased risk of cardiovascular events and increased risk of second malignancies following radiotherapy has led to concern. Most reports refer to patients irradiated with larger target volumes and higher doses but there are also more recent studies reporting on patients treated with more modern radiotherapy [56, 161]. The radiation dose delivered in stage IIA and IIB is approximately 30 Gy and 36 Gy, respectively. The standard radiation field compared with stage I will be extended from the PA region to the ipsilateral iliac field. In stage IIB, the lateral borders should include the metastatic lymph nodes with a safety margin of 1.0-1.5 cm. This technique yields a relapse-free survival in stage IIA and IIB of 92% and 90%, respectively. Overall survival is almost 100% [158, 159]. Conversely, dose reduction to 27 Gy has been associated with 11% of relapses [102, 161].

In stage IIA/B, chemotherapy; with 3 courses of BEP or 4 courses of etoposide and cisplatin (EP) in cases with contraindications to bleomycin is an alternative to radiotherapy. There are no randomised studies comparing radiotherapy versus chemotherapy. Although more toxic in the short term, 3 courses of BEP or 4 courses of EP achieve a similar level of disease control [162]. One population-based study with 67 stage IIB patients reported a relapse free-survival of 100% after a median of 5.5 years of follow-up [102]. Single-agent carboplatin is not an alternative to standard EP or BEP chemotherapy for metastatic disease [163].

Figure 2: Treatment options in patients with seminoma clinical stage II A and B

BEP = cisplatin, etoposide, bleomycin; EP = etoposide, cisplatin.

7.4.2.2 Stage IIA/B non-seminoma

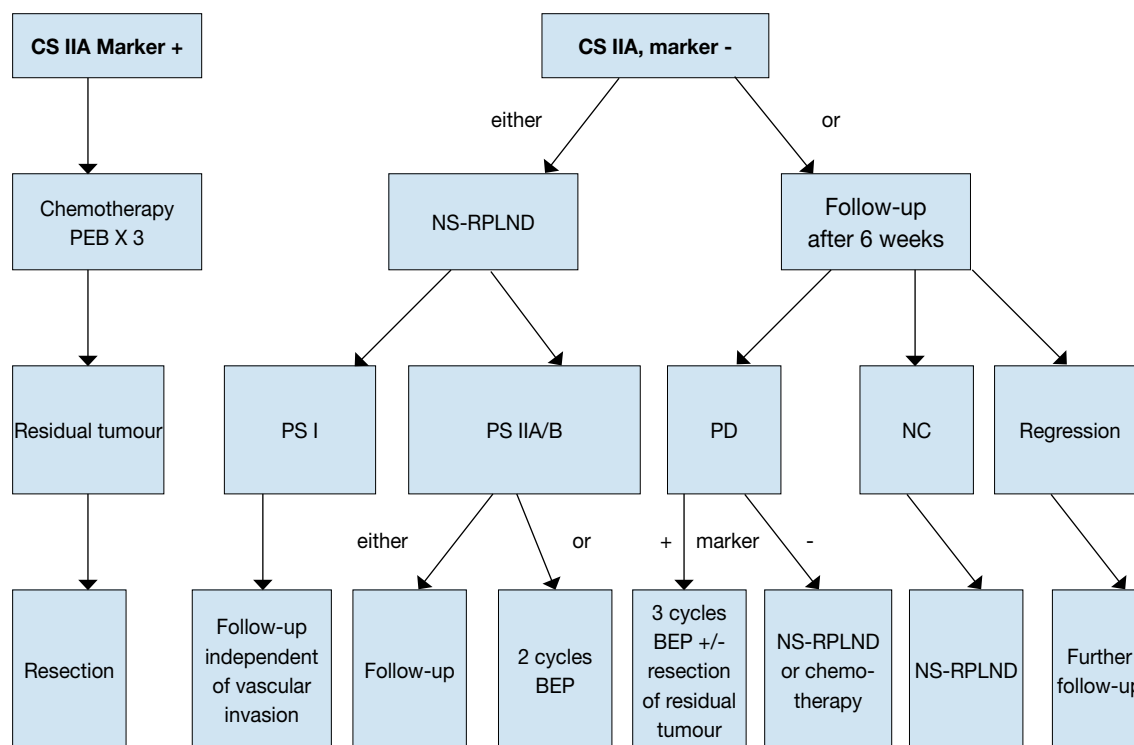

There is a general consensus that treatment should start with initial chemotherapy in all advanced cases of NSGCT except for stage II NSGCT disease without elevated tumour markers, which alternatively can be managed by primary RPLND or surveillance to clarify stage [140, 164, 165].

If surveillance is chosen, one follow-up evaluation after 6 weeks is indicated to document whether the lesion is growing, remaining stable or shrinking. A shrinking lesion is probably non-malignant in origin and should be observed further. A stable or growing lesion indicates either teratoma or an undifferentiated malignant tumour. If the lesion is growing without a corresponding increase in the tumour markers AFP or beta-hCG, RPLND represents the first option to be performed by an experienced surgeon because of suspected viable disease or teratoma [164]. Patients with a growing lesion and a concomitant increase in the tumour markers AFP or beta-hCG require primary chemotherapy with BEP according to the treatment algorithm for patients with metastatic disease and IGCCCG recommendations [166-168] (Figure 2). An alternative to the surveillance strategy in marker-negative II A/B non-seminoma with suspicion of an undifferentiated malignant tumour is a (CT-guided) biopsy, if technically possible. There is insufficient published data on PET scans in this situation.

When primary chemotherapy is refused by the patient or when it has some contraindications, primary nerve-sparing RPLND represents a viable option.

Primary chemotherapy and primary RPLND are comparable options in terms of outcome, but side-effects and toxicity are different, allowing for involvement of the patient in selecting the treatment of choice [169]. The cure rate with either approach will be close to 98% [170-176].

Figure 3: Treatment options in patients with non-seminoma clinical stage IIA

BEP = cisplatin, etoposide, bleomycin; NS = nerve-sparing; RPLND = retroperitoneal lymph node dissection; PS = pathological stage; PD = progressive disease; NC = no change.

7.4.3 Metastatic disease (stage IIC and III)

7.4.3.1 Primary chemotherapy

7.4.3.1.1 Good prognosis risk group - SGCT

For metastatic seminoma, only very limited data are available from randomised trials and they indicate that a cisplatin-based regimen should be preferred to carboplatin chemotherapy [177]. Recent data indicate that EP x 4 result in cure in almost all cases of good-prognosis seminomatous germ cell cancers [178]. Standard treatment in good-prognosis seminoma should therefore be 3 x BEP or 4 x EP. In the case of contraindications to Bleomycin, EP x 4 should be given [179]. Post-chemotherapy masses should be managed as described in Section 7.4.4.1.

7.4.3.1.2 Intermediate prognosis risk group - SGCT

For patients with intermediate-risk seminoma, 4 cycles of BEP or etoposide, cisplatin, ifosfamide (VIP) (in the case of contraindications to bleomycin) are recommended options, although no randomized trial has focused specifically on this group of rare patients [180].

7.4.3.1.3 Good prognosis risk group - NSGCT

For non-seminoma, the primary treatment of choice for metastatic disease in patients with good risk disease according to the IGCCCG risk classification is three cycles of BEP combination chemotherapy (Table 7.1). This regimen has proven superior to cisplatin, vinblastine and bleomycin (PVB) in patients with advanced disease [181-183]. While data support a 3-day regimen of administering combination chemotherapy to be equally effective as a 5-day regimen, this is associated with increased toxicity when four cycles are used [184], thus the 5-day BEP regimen is recommended.

Table 7.1: BEP regimen (interval 21 days)

Drug	Dosage	Duration of cycles
Cisplatin	20 mg/m ²	Days 1-5*
Etoposide	100 mg/m ²	Days 1-5
Bleomycin	30 mg	Days 1, 8, 15

*Plus hydration.

BEP = cisplatin, etoposide, bleomycin.

In selected cases where bleomycin is contraindicated, four cycles of EP can be given [34, 183, 185-187]. A randomised trial from the French Groupe d'Etude des Tumeurs Genito-Urinaires (GETUG) suggested that when the BEP is used in this setting the mortality was half that of EP, although the difference did not reach statistical significance [187, 188].

Therapy should be given without reduction of the doses at 21-day intervals; delaying the following chemotherapy cycle is justified only in cases of fever with granulocytopenia < 1000/mm³ or thrombocytopenia < 100,000/IU. There is no indication for prophylactic application of haematopoietic growth factors such as, for example, granulocyte colony-stimulating factor (G-CSF). However, if infectious complications have occurred during chemotherapy or the treatment interval was delayed due to myelotoxicity, prophylactic administration of G-CSF is recommended for the following cycles [185, 189].

7.4.3.1.4 Intermediate prognosis risk group - NSGCT

The 'intermediate prognosis' group in the IGCCCG has been defined as patients with a 5-year survival rate of about 80%. The available data support four cycles of BEP as standard treatment [34, 190]. A randomised trial has compared 4 cycles of BEP to 4 x BEP with the addition of paclitaxel (T-BEP) and did not show a significant improvement in OS [191]. The overall toxicity with T-BEP was higher than with BEP and thus it cannot be recommended as a standard approach.

7.4.3.1.5 Poor prognosis risk group - NSGCT

For patients with a 'poor prognosis' non-seminoma as defined by the IGCCCG and favourable marker decline, standard treatment consists of four cycles of BEP. Four cycles of cisplatin, etoposide and ifosfamide (PEI) have the same effect, but are more myelotoxic [192, 193]. The 5-year progression-free survival is between 45% and 50%. Three randomised trials have shown no advantage in OS for high-dose chemotherapy for the overall group of 'poor prognosis' patients [194-196].

However, patients with a slow tumour marker decline after the first or second cycle represent a prognostically inferior subgroup [36, 194].

An online calculator is available for free at www.igr.fr/calculation-tumor/NSGCT.xls. Recently, an international randomised phase III trial (GETUG 13) conducted in 263 patients with IGCCCG poor-risk NSGCT demonstrated that intensifying treatment with dose-dense chemotherapy improves PFS, but not OS in patients with an early unfavourable tumour marker decline [37]. Based on the results from this trial, patients with an unfavourable tumour marker decline after one cycle of BEP should be switched to a more intensive chemotherapy regimen [197]. Further prospective trials /registries are planned to validate this approach further.

Since a matched-pair analysis comparing high-dose to conventional treatment resulted in a better survival rate [36, 198, 199], poor prognosis patients should still be treated in ongoing prospective trials or registries, whenever available.

Patients meeting 'poor-prognosis' criteria should be transferred to a reference centre as a better outcome was reported for intermediate and poor prognosis patients who had been treated within a clinical trial in a high volume centre [12, 200]. There are no general recommendations for treatment modifications for patients with a poor general condition (Karnofsky < 50%) or extended liver infiltration (> 50%), but two small reports indicate that a first cycle of dose reduced therapy may reduce acute mortality without compromising long-term outcome, however, the number of subsequent cycles of full dose therapy should not be reduced after a first low dose induction cycle [201, 202].

Patients with extended pulmonary infiltration are at risk for acute respiratory distress syndrome: adapting the doses of the BEP regimen in the first cycle of chemotherapy (only 3 days of EP without bleomycin) was suggested to reduce the risk of early death in this setting [201].

7.5 Restaging and further treatment

7.5.1 Restaging

Restaging is performed by imaging investigations and re-evaluation of tumour markers. At marker decline and stable or regressive tumour manifestation, chemotherapy will be completed (three or four cycles, depending on

the initial stage) [34, 203, 204]. In the case of marker decline, but growing metastases, resection of the tumour is obligatory after termination of induction therapy, other than in an emergency, according to local tumour growth [205].

Only with documented marker increase after two courses of chemotherapy is an early crossover of therapy to a completely new regimen indicated. These patients are usually candidates for new drug trials [198, 206]. Patients with a low-level hCG marker plateau post-treatment should be observed to see whether complete normalisation occurs. In patients with a low plateau serum AFP level after chemotherapy, surgery of residual masses should be performed, with post-surgery AFP monitoring. Salvage chemotherapy is indicated for documented marker rise only [207, 208].

7.5.2 **Residual tumour resection**

7.5.2.1 *Seminoma*

A residual mass of seminoma should not be primarily resected, irrespective of the size, but controlled by imaging investigations and tumour markers [209-215].

FDG-PET has a high negative predictive value in patients with residual masses after treatment of seminoma. False positive results are less frequent when scans are scheduled >2 months after chemotherapy. In patients with residuals of > 3 cm, FDG-PET should be performed in order to gain more information on the viability of these residuals. In patients with residuals of < 3 cm, the use of FDG-PET is optional [49].

In the case of a post-chemotherapy mass that is still positive at reclassification FDG-PET with no volume increase, a second FDG-PET should be performed 6 weeks later. Alternatively, a biopsy should be taken to ascertain persistent disease. In these cases as well as in those with progressive disease (i.e. a growing mass which up-takes contrast medium at CT scans or radionuclide tracer at FDG-PET), salvage therapy is indicated (usually chemotherapy or radiotherapy) [216-220]. Patients with persistent and progressing hCG elevation after 1st line chemotherapy should immediately proceed with salvage chemotherapy. Progressing patients without hCG progression should undergo histological verification (e. g. by biopsy or mini-invasive or open surgery) before salvage chemotherapy is given.

When RPLND is indicated, this should be performed in referral centres, as residuals from seminoma may be difficult to remove due to intense fibrosis [219]. Ejaculation may be preserved in these cases [221].

7.5.2.2 *Non-seminoma*

Following first-line BEP chemotherapy, only 6-10% of residual masses contain viable cancer, 50% contain mature teratoma, and 40% contain necrotic-fibrotic tissue [222].

FDG-PET is not indicated to re-stage patients after chemotherapy [52]. In cases of complete remission after 1st line chemotherapy (no visible tumour), tumour resection is not indicated [223-227].

Residual tumour resection is mandatory in all patients with a residual mass > 1 cm in the short axis at cross-sectional CT imaging [224, 225, 228-237].

The role of surgery is debated in patients with retroperitoneal residual lesions < 1 cm. There is still a risk of residual cancer or teratoma although the vast majority of patients (> 70%) harbour fibro-necrotic tissue [238, 239]. Proponents of PC-RPLND for all patients refer to the fact that both teratoma and vital malignant germ cell tumours are still found after radiologic complete remission in lesions < 10 mm [240]. The alternative is to put patients with residual disease < 1 cm on an observation protocol based on recurrence data of 6-9% depending on the time of follow-up [226, 227]. In the series with the longer observation of 15.5 years, 12 of 141 patients (9%) relapsed after having achieved a complete response after primary treatment [227], but eight of the 12 relapsing patients were cured. Therefore, patients treated with 1st line chemotherapy should be informed about this life-long risk of recurrence in the order of 10% before consenting to observe residual lesions < 1 cm. Patients after salvage chemotherapy or high-dose chemotherapy in 1st or subsequent salvage situations harbour vital tumour at a much higher rate [241]. Therefore, there is an indication to perform surgery in salvage patients even with residual disease < 1 cm [226, 227].

If residual surgery is indicated, all areas of primary metastatic sites must be completely resected within 2-6 weeks of completion of chemotherapy. If technically feasible, a bilateral nerve-sparing procedure should be performed. There is growing evidence that "template" resections with unilateral preservation of nerves in selected patients yield equivalent long-term results compared to bilateral systematic resections in all patients. The mere resection of the residual tumour (so called "lumpectomy") should not be performed. [223, 227-229, 238, 239, 242-250].

In persistent larger volume retroperitoneal disease, all areas of primary metastatic sites must be completely resected within 2-6 weeks of completion of chemotherapy. If technically feasible, a nerve-sparing procedure should be performed [223, 227-229, 238, 239, 242-246].

Laparoscopic RPLND may yield similar outcomes to the open procedure in very selected cases of very low residual disease and in very experienced hands, but it is not recommended outside a specialised laparoscopic centre [251-253].

7.5.3 Timing of surgery in the case of multiple sites

In general, residual surgery should start at the location with the highest volume of residual disease. The histology may diverge in different organ sites [231]. In cases of retroperitoneal and lung residual masses, the presence of fibro-necrotic tissue in the retroperitoneum is associated with a probability as high as 90% that lung masses contain the same histology [254].

Resection of contralateral pulmonary lesions is not mandatory in case pathologic examination of the lesions from the first lung shows complete necrosis. However, discordant histologies between both lungs may occur in up to 20% [255, 256].

7.5.3.1 Quality and intensity of surgery

Post-chemotherapy surgery is always demanding. Most of the time, post-chemo RPLND does not require further interventions on abdominal or retroperitoneal organs. About a third of patients may require a planned intervention where removal of organs affected by the disease (for example kidney, psoas muscle or gross vessels) are provided and followed by ad hoc reconstructive surgery (e.g. vascular interventions such as vena cava or aortic prostheses) [257, 258]. In patients with intermediate or poor risk and residual disease > 5 cm the probability of vascular procedures is as high as 20% [259]. This intense ("maximal") surgery must therefore be referred to specialised centres capable of interdisciplinary surgery (hepatic resections, vessel replacement, spinal neurosurgery, thoracic surgery). Patients treated within such centres benefit from a significant reduction in perioperative mortality from 6% to 0.8% [13]. In addition, specialised urologic surgeons are capable of reducing the local recurrence rate from 16% to 3% with a higher rate of complete resections [14].

7.5.3.2 Salvage and desperation surgery.

Surgery of resectable disease after salvage treatment remains a potentially curative option in all patients with any residual mass following salvage chemotherapy. Survival after surgery and first salvage chemotherapy was improved (70% at 10 years) following taxane-containing regimens [260]. Also, in the case of extensive salvage chemotherapy, surgery remains a fundamental tool to achieve durable complete remissions in up to 20% of patients [261, 262].

Desperation surgery refers to resection of non-responsive or progressive (e.g. rising markers) disease following salvage chemotherapy. When the disease is resectable, a significant proportion of these patients can be rendered disease-free in the long term [263].

7.5.3.3 Consolidation chemotherapy after secondary surgery

After resection of necrosis or mature/immature teratoma, no further treatment is required. In cases of incomplete resection of viable cancer, two adjuvant cycles of conventionally dosed cisplatin-based chemotherapy may be given in certain subgroups (e.g. 'poor prognosis' patients) [247] (caution: cumulative doses of bleomycin). After complete resection of 'vital' tumour < 10% of the total volume, especially in patients in an initially good prognosis group according to IGCCCG, the relapse rate is very low and adjuvant chemotherapy is not beneficial for preventing further relapse [264]. The prognosis will definitely deteriorate if vital malignant neoplasm is found in resection specimens after second- and third-line chemotherapy. In this latter situation, post-operative chemotherapy is not indicated and is unable to improve the prognosis [239, 265].

7.5.4 Systemic salvage treatment for relapse or refractory disease

Cisplatin-based combination salvage chemotherapy will result in long-term remissions in about 50% of the patients who relapse after first-line chemotherapy, but the results are highly dependent on several prognostic factors [266]. The regimens of choice are four cycles of a triplet regimen including cisplatin and ifosfamide plus a third agent: etoposide (PEI/VIP), paclitaxel (TIP), or potentially gemcitabine (GIP) (Table 7.2) [267]. No randomised trial has ever compared these regimens. Due to their potentially lethal risk of haematological toxicity, these regimens should be used with G-CSF support and by well-trained oncologists.

The only available randomised trial comparing standard-dose versus high-dose chemotherapy plus transplant in the salvage setting showed no benefit in OS in patients treated with 3 cycles of vinblastine, ifosfamide, and cisplatin (VeIP) plus 1 cycle of consolidation high-dose chemotherapy, compared with 4 cycles of VeIP [268]. At present, it is impossible to determine whether conventionally dosed cisplatin-based combination chemotherapy is sufficient as first-salvage treatment or whether early intensification of first-salvage treatment with high-dose chemotherapy should be used. However, there is evidence from large retrospective analyses that there are different prognostic groups in the case of relapse after first-line

chemotherapy [269-271], and the Lorch-Beyer score has resulted in 5 prognostic subgroups (Table 7.3). A second large analysis in this cohort of 1600 patients showed an improvement of about 10-15% in OS in patients from all prognostic subgroups when treated with high-dose salvage therapy compared to standard dose therapy. To prospectively confirm this finding, an international randomised trial of high-dose versus conventional dose chemotherapy in patients with first-line relapse is planned (Tiger trial). If high-dose chemotherapy is used as a salvage treatment, sequential treatment cycles of high-dose carboplatin and etoposide HD-CE should be preferred to a single high-dose regimen because the former is associated with less toxicity-related deaths [272].

It is clearly of the utmost importance that these rare patients with relapse are treated within clinical trials and at experienced centres.

Table 7.2: Standard PEI/VIP, TIP and GIP chemotherapy (interval 21 days)

Chemotherapy agents	Dosage	Duration of cycles
PEI/VIP		
Cisplatin*	20 mg/m ²	Days 1-5
Etoposide	75-100 mg/m ²	Days 1-5
Ifosfamide†	1.2 g/m ²	Days 1-5
TIP		
Paclitaxel	250 mg/m ² ^{xx}	24 hour continuous infusion day 1
Ifosfamide†	1.5 g/m ²	Days 2-5
Cisplatin*	25 mg/m ²	Days 2-5
GIP		
Gemcitabine	1000 mg/m ²	Day 1 + 5
Ifosfamide	1200 mg/m ²	Days 1-5
Cisplatin	20 mg/m ²	Days 1-5

PEI/VIP = cisplatin, etoposide, ifosfamide; TIP = paclitaxel, ifosfamide, cisplatin; GIP = gemcitabine, ifosfamide, cisplatin

* Plus hydration.

† Plus mesna protection.

^{xx} An MRC schedule uses paclitaxel at 175 mg/m² in a 3 hour infusion [273].

The International Prognostic Factors Study Group score comprised of 7 important factors is listed in Table 7.3 (seminoma vs. non-seminoma histology, primary tumour site, response to initial chemotherapy, duration of progression-free interval, AFP marker level at salvage, hCG marker level at salvage, and the presence of liver, bone, or brain metastases at salvage). Using these factors, 5 risk groups (very low risk = -1 points; low risk = 0 points; intermediate-risk = 1-2 points, high risk = 3-4 points; and very high risk ≥ 5 points) were identified with significant differences in PFS and OS. Table 4.3 illustrates the 5 risk groups and the corresponding 2-year PFS and 3-year OS rates [274].

Table 7.3: The International Prognostic Factors Study Group Score Construction [270]

Points	-1	0	1	2	3
Variable					
Histology	Seminoma	Non-seminoma			
Primary site		Gonadal	Retroperitoneal		Mediastinal
Response		CR/PRm-	PRm+/SD	PD	
PFI		> 3 months	≤ 3 months		
AFP salvage		Normal	< 1000	1000	
hCG salvage		< 1000	1000		
LBB		No	Yes		

AFP = alpha-fetoprotein; hCG = human chorionic gonadotrophin; LBB = liver, bone, brain metastases;

PFI = progression-free interval.

Table 7.4: PFS and OS estimates for all patients according to IGCCCG-2 prognostic score [270]

	n	%	HR	2-year PFS	3-year OS
Score (n=1435)					
Very Low	76	5.30	1	75.1	77.0
Low	257	17.9	2.07	52.6	69.0
Intermediate	646	45.0	2.88	42.8	57.3
High	351	24.5	4.81	26.4	31.7
Very High	105	7.3	8.95	11.5	14.7
Missing	159				

IGCCCG = International Germ Cell Cancer Collaborative Group; OS = overall survival; PSF = progression-free survival.

7.5.5 Second relapse

There are no randomised trials for patients with second relapse; however, conventional therapy does not appear to be very effective. For patients having received two series of conventionally dosed therapy (first-line and first salvage), HD chemotherapy with autologous stem cell support should be used [270]. Even with HD-therapy the curative chance is only 20-25%.

Refractory disease: Patients relapsing within 4-8 weeks after platinum-based therapy or who are progressing despite platinum-based therapy as well as those relapsing shortly after HD-CTX are considered cis-platinum refractory. For those patients, combinations of gemcitabine and oxaliplatin or the triple combination of gemcitabine, oxaliplatin and paclitaxel have resulted in response rates of 25-45%. Cisplatin re-challenge in association with gemcitabine and paclitaxel, could be considered in patients with good renal function [275]. Those patients with a good response undergoing subsequent resection of residual tumour lesions may still have a 15-20% chance of long-term cure [261].

7.5.5.1 Late relapse (≥ 2 years after end of first-line treatment)

Late relapse is defined as recurrence more than 2 years following cure after chemotherapy for metastatic TC, with, or without, residual tumour surgery and occurs, according to a pooled analysis, in 1.4% and 3.2% in seminoma and non-seminoma patients, respectively [276, 277]. If feasible, all lesions of late relapsing non-seminoma patients should be removed by radical surgery.

Patients with rapidly rising hCG may benefit from induction salvage chemotherapy before complete resection, but in most patients surgery should be performed irrespective of the level of their tumour markers in order to completely resect all undifferentiated germ-cell tumour, mature teratoma with or without somatic transformation [138, 278, 279].

Survival strongly depends on the histology of the removed lesions rather than on the initial germ cell cancer. Interestingly, in a population-based study all late-relapsing seminoma patients had viable germ cell tumour, whereas teratoma or necrosis was found in half of the patients with initial non-seminoma [280].

If the lesions are not completely resectable, biopsies should be obtained for histological assessment, and salvage chemotherapy should be initiated according to the histological results. In these cases, consultation of an experienced pathologist is required to avoid misinterpretation of the therapeutic morphological changes in the germ cell neoplasms [281]. If the patient responds to salvage chemotherapy, secondary surgery should be conducted whenever possible. In the case of unresectable, but localised, refractory disease, stereotactic or conventional radiotherapy may be considered. To avoid excess mortality, late relapses should be treated only at centres experienced in managing such patients [282].

7.5.5.2 Treatment of brain metastases

Brain metastases occur in the frame of a systemic relapse and rarely as an isolated relapse. The long-term survival of patients presenting with brain metastases at initial diagnosis is poor (30-50%), but it is even poorer when brain metastasis develops as recurrent disease (the 5-year survival-rate is 2-5%) [283, 284]. Chemotherapy is the initial treatment in this case, and some data support the use of consolidation radiotherapy, even in the case of a total response after chemotherapy [285]. Surgery can be considered in the case of a persistent solitary metastasis, depending on the systemic state, the histology of the primary tumour and the location of the metastasis.

	LE	GR
Low volume NSGCT stage IIA/B with elevated markers should be treated like 'good or intermediate prognosis' advanced NSGCT, with three or four cycles of BEP.	2	A
In stage IIA/B without marker elevation, histology can be gained by RPLND or biopsy. A repeat staging can be performed after six weeks of surveillance before final decision on further treatment.	3	B
In metastatic NSGCT (\geq stage IIC) with a good prognosis, three courses of BEP is the primary treatment of choice.	1	A
In metastatic NSGCT with an intermediate prognosis, the primary treatment of choice is four courses of standard BEP.	1	A
In metastatic NSGCT with a poor prognosis, the primary treatment of choice is one cycle of BEP, followed by tumour marker assessment after 3 weeks: in the case of an unfavourable decline, chemotherapy intensification should be initiated; in the case of a favourable decline, BEP should be continued up to a total of four cycles.	1	A
Surgical resection of residual masses after chemotherapy in NSGCT is indicated in the case of visible residual masses and when serum levels of tumour markers are normal or normalising.	2	A
Seminoma CSII A/B can initially be treated with radiotherapy. When necessary, chemotherapy can be used as a salvage treatment with the same schedule as for the corresponding prognostic groups of NSGCT.	2	B
In seminoma stage CS IIA/B, chemotherapy (3 x BEP or 4 x EP, in good prognosis) is an alternative to radiotherapy. It appears that 3 x BEP or 4 x EP achieve a similar level of disease control.	3	B
Seminoma stage IIC and higher should be treated with primary chemotherapy according to the same principles used for NSGCT.	1	A

EP = epirubicin, cisplatin; GR = grade of recommendation; NSGCT = non-seminomatous germ cell tumour; BEP = cisplatin, epirubicin, bleomycin; RPLND = retroperitoneal lymph node dissection.

8. FOLLOW-UP AFTER CURATIVE THERAPY

8.1 Follow-up care for cancer patients

There is no consensus on a standardised follow-up of patients treated for germ-cell cancer.

8.2 General considerations

The following considerations apply in a general manner for the selection of an appropriate schedule and testing in the follow-up of all stages of testis tumour.

- Most recurrences after curative therapy will occur in the first 2 years; surveillance should therefore be most frequent and intensive during this time.
- Late relapses can occur beyond 5 years, and therefore yearly follow-up for life may be advocated.
- After RPLND, relapse in the retroperitoneum is rare, the most likely site of recurrence being the chest.
- The value of a plain radiography chest has been recently questioned in the follow-up of patients with disseminated disease after complete remission [286, 287].
- CT of the chest has a higher predictive value than plain radiography chest [287].
- The results of therapy are dependent on the bulk of disease; thus an intensive strategy to detect asymptomatic disease may be justifiable.
- After chemotherapy or radiotherapy, there is a long-term risk of the development of secondary malignancies.
- Exposure to diagnostic X-rays causes second malignancies [288]. Thus, the frequency of CT scans should generally be reduced and any exposure to X-rays should be well justified in a patient cohort with a very long life-expectancy after successful treatment.
- CT can be substituted by MRI. However, MRI is a protocol-dependent method and, thus, should be performed in the same institution with a standardised protocol.
- With special expertise, US may be used as a method to screen the retroperitoneum during follow-up.

However, the method is very much dependent on the investigator and cannot be recommended as the standard method during follow-up.

- Longer follow-up in patients after radiotherapy and chemotherapy is justified to detect late toxicities (e.g. cardio-vascular, endocrine).

A number of interdisciplinary organisations have presented recommendations for follow-up of testicular cancer patients [289-291]. The follow-up tables below (Tables 8.1 through 8.4) present the minimum recommendations of the expert opinions of the guideline authors.

8.3 Follow-up: stage I non-seminoma

Approximately 5% of patients with CS1 NSGCT present with elevated levels of tumour markers after orchiectomy, and up to 25-30% relapse during the first 2 years [7, 128, 130, 131, 171, 292-295]. The follow-up schedule will differ depending on which of the three possible treatment strategies was chosen:

- surveillance;
- nerve-sparing RPLND;
- adjuvant chemotherapy.

8.3.1 Follow-up investigations during surveillance

The results of a surveillance policy depend upon a careful pre-operative staging procedure and follow-up management. In a 'wait and see' policy, relapses will occur in 30% of cases. Of these relapses, 80% will occur in the first 12 months after orchiectomy, and approximately 12% during the second year. The median time to relapse is 6 months (range 1-62 months), but relapses after 3-5 years, and even later, can still occur, with an annual rate of 4% [108, 109]. Relapse occurs mainly in the retroperitoneum: approximately 70% of patients have evident metastases in the retroperitoneum, and 10% in the mediastinum and lungs [296]. Sometimes the only indication is an elevated level of tumour markers.

A randomised trial of two versus five CTs has been published by the MRC recommending the reduction of imaging during surveillance in this stage to one CT scan at 3 months after orchiectomy, and another at 12 months. The trial, with a cohort of 414 patients, was powered to exclude a 3% probability of detecting a patient during surveillance only, with a relapse presenting already-metastatic disease with 'intermediate' or 'poor' prognosis features. Relapses were detected in 15% with two CTs, and 20% with five CTs; 1.6% of these patients had 'intermediate' or 'poor' prognostic features. Only 10% of patients had high-risk features (vascular invasion). In summary, this first randomised trial yielded level 1 evidence for a minimum follow-up in patients with CS1 non-seminoma [142]. The recommended follow-up schedule (Table 8.1) includes the minimum requirements for imaging, and adds recommendations for other surveillance tests [296].

Table 8.1: Recommended minimum follow-up schedule in a surveillance policy: stage I non-seminoma [296]

Procedure	Year			
	1	2	3	4-5
Physical examination	4 times	4 times	4 times	Once/year
Tumour markers	4 times	4 times	4 times	Once/year
Plain radiography chest	Twice		Twice	
Abdominopelvic CT	Twice (at 3 and 12 months)		Once in year 2 (at 24 months) Once in year 3 (at 36 months)	

CT= computed tomography.

8.3.2 Follow-up after nerve-sparing RPLND

Retroperitoneal relapse after a properly performed nerve-sparing RPLND is rare. RPLND should eliminate the retroperitoneal nodes as a site of relapse and thus the need for repeated abdominal CTs. The US Testicular Cancer Intergroup study data show retroperitoneal relapse in 7/264 patients with pathological stage I disease (and 20 pulmonary relapses); four of these seven had no marker elevation [297]. In the Indiana series, only one relapse in 559 cases was reported [298]. If a relapse occurs, it is generally in the chest, neck or at the margins of the surgical field.

Pulmonary relapses occur in 10-12% of patients, and more than 90% of those relapses occur within 2 years of RPLND [55, 299]. However, the low rate of retroperitoneal relapse after RPLND can only be achieved by surgery in specialised centres, as shown by the high in-field relapse rate (7/13 relapses) in the German randomised trial

of RPLND versus one course of BEP [135]. The recommended minimum follow-up schedule is shown in Table 8.2.

Table 8.2: Recommended minimum follow-up schedule after retroperitoneal lymphadenectomy or adjuvant chemotherapy: stage I non-seminoma

Procedure	Year				
	1	2	3	4-5	6-10
Physical examination	4 times	4 times	4 times	Once/year	Once/year
Tumour markers	4 times	4 times	4 times	Once/year	Once/year
Plain radiography chest	Twice	Twice	Twice		
Abdominopelvic CT	Once	Once	Once	Once/year	

CT = computed tomography.

8.3.3 Follow-up after adjuvant chemotherapy

Prospective reports with long-term follow-up after adjuvant chemotherapy have shown a low relapse rate of about 3% [128-131]. In a randomised trial with one course of BEP versus RPLND, the relapse rate with adjuvant chemotherapy was 1% (2/174 patients, one with marker relapse, one with mature teratoma in the retroperitoneum) [135]. The need for repeated and long-term assessment of the retroperitoneum is still not clear. Owing to the risk of developing a late, slow-growing teratoma in the retroperitoneum after adjuvant chemotherapy, an abdominal CT should still be performed (see Table 8.2).

8.4 Follow-up: stage I seminoma

The majority of patients with seminoma (70-80%) present with clinical stage I disease at diagnosis. In 15-20% of cases, there is nodal radiological involvement at the level of the retroperitoneum, and only 5% of patients present with distant metastasis.

The relapse rate varies between 1% and 20%, depending on the post-orchietomy therapy chosen. Only up to 30% of seminomas present with elevation of hCG at diagnosis or in the course of the disease. Consequently, in most cases, measurement of blood markers will not be a reliable test for follow-up [300]. The treatment options post-orchietomy in stage I seminoma are surveillance or adjuvant carboplatin chemotherapy.

8.4.1 Follow-up after radiotherapy

Low doses of radiotherapy (20-24 Gy) limited to the retroperitoneal or the paraaortic and ipsilateral field achieve an OS rate of approximately 99% at 5-10 years [108-110, 301, 302]. The rate of relapse is 1-2% and the most common time of presentation is within 18 months of treatment [108, 111, 302-304], although late relapses have also been described [278]. The site of relapse is mainly at the supradiaphragmatic lymph nodes, mediastinum, lungs or bones. In a small proportion of cases, the tumour will relapse in the inguinal or external iliac nodes. After para-aortic field RT there is also a pelvic node relapse pattern.

The side-effects of radiotherapy include temporary impaired spermatogenesis, GI symptoms (peptic ulceration), and induction of second malignancies [303, 305, 306]. Up to 50% of patients can develop moderate toxicity grade I-II [300]. The follow-up schedule is described in Table 8.3.

Table 8.3: Recommended minimum follow-up schedule for post-orchietomy surveillance, radiotherapy or chemotherapy: stage I seminoma [295]

Procedure	Year		
	1	2	3-5
Physical examination	3 times	3 times	Once/year
Tumour markers	3 times	3 times	Once/year
Plain radiography chest	Twice	Twice	
Abdominopelvic CT	Twice	Twice	at 36 and 60 months

CT = computed tomography.

8.4.2 Follow-up during surveillance

The actuarial risk of relapse at 5 years ranges between 6% (low risk) and 20% [114, 307-311]. There is no increased risk of death. The median time to relapse ranges from 12-18 months, but up to 29% of relapses can develop later than this [99, 312]. The sites of relapse are the PA lymph nodes in up to 82% of cases; the pelvic

lymph nodes, inguinal nodes and lungs can also be affected [99, 134, 313-316]. Due to the high and often late rate of relapse, close and active follow-up is mandatory for at least 5 years [307] (see Table 8.3).

8.4.3 Follow-up after adjuvant chemotherapy

One or two courses of carboplatin-based chemotherapy is an effective alternative treatment in stage I seminoma. The relapse rate is 1.9-4.5%. In general, this treatment is well tolerated, with only mild, acute and intermediate-term toxicity [307, 308]. Long-term data on late relapses and survival are missing (see Table 8.3).

8.5 Follow-up: (metastatic) disease

The more advanced the nodal stage of the disease, the higher the likelihood of recurrence [170]. In general, the primary tumour bulk governs the outcome for patients with NSGCT [312]. In stage II NSGCT, regardless of the treatment policy adopted, excellent survival rates of 97% are reached provided that relapse is identified as soon as possible [140, 165, 172].

In advanced metastatic germ-cell tumours, the extent of the disease correlates with the response to therapy and with survival. The combination of cisplatin-based chemotherapy and surgery (aggressive multimodality) achieves cure rates of between 65% and 85%, depending on the initial extent of disease [310, 311]. Complete response rates to chemotherapy are in the order of 50-60% [310]; another 20-30% of patients could be disease-free with post-chemotherapy surgery [317].

The main reasons for failure of therapy in advanced NSGCT are [34, 309, 318]:

- the presence of bulky disease not responding completely to chemotherapy;
- unresectable residual teratoma after chemotherapy;
- the presence or development of chemoresistant non-germ elements, which account for 8.2% of cases.

Table 8.4 presents the recommended minimum follow-up schedule in advanced NSGCT and seminoma.

Table 8.4: Recommended minimum follow-up schedule in metastatic NSGCT and seminoma

Procedure	Year			
	1	2	3-5	Thereafter
Physical examination	4 times	4 times	Twice/year	Once/year
Tumour markers	4 times	4 times	Twice/year	Once/year
Plain radiography chest	4 times	4 times	Twice/year	Once/year
Abdominopelvic CT [†]	Twice	Twice	Once/year	As indicated
Chest CT [‡]	Once/year	Once/year	Once/year	As indicated
Brain CT [§]	Once/year	Once/year	Once/year	As indicated

CT = computed tomography.

* An abdominal CT must be performed at least annually if teratoma is found in the retroperitoneum.

† If the post-chemotherapy evaluation in a seminoma patient shows any mass > 3 cm, the appropriate CT should be repeated 2 and 4 months later to ensure that the mass is continuing to regress. If available, FDG-PET/CT can be performed.

‡ A chest CT is indicated if abnormality is detected on a plain radiography chest and after pulmonary resection.

§ In patients with headaches, focal neurological findings, or any central nervous system symptoms.

8.6 Quality of life and long-term toxicities after cure for testicular cancer

The vast majority of patients will be cured and 5-year relative survival rates approximate 95% in Western Europe. Furthermore, TC patients are usually between 18 and 40 years at diagnosis such that life expectancy after cure extends over several decades [319]. Patients should be informed before treatment of common long-term toxicities, which are probably best avoided by adherence to international guidelines. Treatment of stage I TC is controversial with some experts advocating surveillance for all, thereby avoiding unnecessary adjuvant chemotherapy [126], whereas others highlight the importance of patient autonomy and consider the prospect of avoiding salvage treatment with its known long-term toxicities as quite appealing [320]. Unfortunately, we do not know which treatment spares most patients long-term toxicities, which so far seem to be absent or mild after adjuvant chemotherapy [131, 139, 321].

During follow-up, patients should be screened and treated for known risk factors such as high blood pressure, hyperlipidaemia and testosterone deficiency. When follow-up by the TC expert is discontinued, a written cancer survivorship plan addressing late toxic effects, lifestyle recommendations, recurrence risk, and cancer-specific follow-up might be helpful [277, 322]. The following overview is not complete and interested readers are referred to review articles on this topic [319, 322, 323].

8.6.1 **Second malignant neoplasms (SMN)**

Treatment-induced SMN usually occur after the first 10 years [322]. The risk for solid SMN increases with younger age at radio- or chemotherapy and remains significantly elevated for at least 35 years [111, 115, 324-326]. RT-related SMN are primarily localised within or close to the RT field (colon, stomach, pancreas, bladder and the urinary tract) [111, 112, 115, 116, 325-328]. Fung et al. demonstrated that modern cisplatin-based chemotherapy was associated with a 40% increased risk of a solid SMN [329].

8.6.2 **Leukaemia**

In a series of 40,576 TC survivors, the observed/expected ratio for developing a leukaemia, mostly acute myeloid (AML) and lymphoblastic leukaemias was 2.6 (95% CI, 2.1 to 3.2) [330]. The risk of AML seems to be both related to the dose of cisplatin and etoposide. Doses of etoposide exceeding 2 g/m² have been shown to increase the subsequent risk of AML considerably [331]. It is important to keep in mind that the majority of TC patients do receive much lower doses of etoposide such that the absolute risk of AML after three to four courses of BEP is very low, and in patients requiring high-dose chemotherapy with cumulative etoposide doses exceeding this threshold, less than 1.5% have been reported to suffer from AML. There is a cumulative dose-disease relationship regarding cisplatin and AML. Chemotherapy-induced leukaemia is usually diagnosed within the first 10 years after treatment for TC and has a very poor prognosis [332].

8.6.3 **Infections**

Chemotherapy-treated testicular cancer survivors (TCSs) have a higher risk of dying from infections than the normal population, SMR 2.48, 95% CI: 1.70 to 3.50 [333]. This is possibly due to long-term depression of the bone-marrow, but also complications of subsequent salvage treatment (which was not reliably registered) or extensive or subsequent surgical treatment might lie behind these numbers. Furthermore, asymptomatic pulmonary fibrosis by mediastinal radiotherapy and/or bleomycin may render TCSs vulnerable to potentially deadly pneumonias many years after treatment.

8.6.4 **Pulmonary complications**

Chemotherapy exposed TCSs have a nearly 3-fold increased risk of dying of pulmonary diseases than the normal population [333]. Bleomycin-induced lung toxicity may affect 7% to 21% of patients in the long-term, resulting in death in 1%-3% [334]. TCSs treated with high cumulative cisplatin doses and/or pulmonary surgery, have a poorer pulmonary function than those cured by surgery only [335]. Intriguingly, pulmonary complications were associated with the cumulative cisplatin dose and not to the dose of bleomycin.

8.6.5 **Cardiovascular toxicity**

Mortality from cardiovascular disease (CVD) is higher in TCSs than in the general population [333, 336]. Furthermore, CVD is more common in chemotherapy-treated TCSs than in those who underwent surgery only [134, 315]. The metabolic syndrome is a strong predictor for CVD and its components, i.e. hypertension, obesity and hypercholesterolemia, increase with treatment intensity [316, 337]. Circulating residual serum platinum might exert endothelial stress [338].

8.6.6 **Raynaud-like phenomena**

Chemotherapy-related Raynaud-like phenomena were reported before the introduction of cisplatin and are usually ascribed to the application of bleomycin [339, 340]. Cisplatin is believed to contribute to cold-induced vasospasms, as Vogelzang et al. reported that the incidence of Raynaud's phenomenon was higher after treatment with CVB than after vinblastine and bleomycin only (41% vs. 21%, respectively) [341].

8.6.7 **Neurotoxicity**

Cisplatin induces a symmetric dose-dependent sensory, distal, length-dependent "glove and stocking" paraesthesias, affecting 29% of TCSs who received cisplatin-based chemotherapy as opposed to 10% after orchiectomy alone [342]. Application of five or more cycles increases the frequency of this symptom to 46%. Paclitaxel-induced acute neuropathy consists of an acute pain syndrome, which usually develops within three days of paclitaxel administration, or within a week. Platinum is measurable in the serum of TCSs many years after its application and the intensity of paraesthesias is more strongly associated with platinum serum level than with the cumulative dose of applied cisplatin [338].

8.6.8 **Ototoxicity**

Cisplatin-induced ototoxicity comprises tinnitus and hearing impairment, particularly of high frequencies of 4000 Hz and higher, and is caused by damage to the outer hair cells in the inner ear [343-345]. Both hearing impairment and tinnitus are considerably increased after application of 50 mg/m² cisplatin over two days as compared to 20 mg/m² over five days (odds ratio 5.1 and 7.3, respectively), indicating a higher impact of serum

peak concentrations than cumulative doses [342]. A significant association between GST genotypes and the risk of cisplatin-induced ototoxicity has been demonstrated [346, 347]. Hopefully, increasing insight into the pathogenesis of and vulnerability for this complication will lead to more individualised treatment in the future.

8.6.9 Nephrotoxicity

Cisplatin-based chemotherapy may lead to long-term renal function impairment in 20-30% of TCSs [342-345]. In testicular cancer patients, reduced renal elimination of cisplatin and bleomycin might increase the risk of other toxicities, e.g. bleomycin-related pneumonitis [348, 349].

8.6.10 Hypogonadism

Testicular endocrine dysfunction comprises insufficient testosterone (T) production and/or compensatory increased Luteinizing Hormone (LH) levels. Subnormal testosterone levels have been reported in TCs treated with chemotherapy compared with surgery only or the general population [322, 350].

8.6.11 Fatigue

Chronic fatigue (CF) is described as a subjective feeling of emotional, physical and/or cognitive tiredness that is not relieved by rest, persisting for more than 6 months. Significantly higher levels of C-reactive protein and interleukin-1 receptor antagonist are measured in TCSs with CF [351]. Also, a significantly higher frequency of CF (16%) was reported in a cross-sectional Norwegian study of long-term TCSs a median of 12 years after treatment for TC when compared with the age-matched Norwegian population (10%) [352]. Of note; the prevalence of CF increased from 15% to 27% during 10 years in long-term TCSs [353].

8.6.12 Quality of life

Quality of life (QoL) is transiently reduced by chemotherapy, during which patients experience a loss of appetite, increased fatigue, increased dyspnoea, reduced social-, physical- and role-functions [354]. When comparing three or four cycles of BEP in good risk patients, all outcomes favour treatment with three courses [184]. After 1 and 2 years, one third of patients reported an improvement in global QoL after chemotherapy, while one fifth of patients reported deterioration, with no difference between treatment groups. In adjuvant treatment of non-seminoma stage I patients, there was no difference in short-term or long-term (5 year) QoL between RPLND or one course of BEP [355].

9. TESTICULAR STROMAL TUMOURS

9.1 Classification

Non-germ-cell tumours of the testicle include sex cord/gonadal stromal tumours and miscellaneous non-specific stromal tumours. The different histological subtypes of testicular tumours are defined according to the WHO classification 2004 (adapted) [32].

9.2 Leydig cell tumours

9.2.1 Epidemiology

Leydig cell tumours constitute about 1-3% of adult testicular tumours [356, 357] and 3% of testicular tumours in infants and children [357]. These tumours are most common in the third to sixth decade in adults, with a similar incidence observed in each decade. Another peak incidence is seen in children aged between 3 and 9 years. Only 3% of Leydig cell tumours are bilateral [356]. These tumours occur in about 8% of patients with Klinefelter's syndrome [358].

9.2.2 Pathology of Leydig cell tumours

Leydig cell tumours are the most common type of sex cord/gonadal stromal tumours. Histopathologically, they are well delineated and usually up to 5 cm in diameter. They are solid, yellow to tan in colour, with haemorrhage and/or necrosis in 30% of cases. Microscopically, the cells are polygonal, with eosinophilic cytoplasm and occasional Reinke crystals, regular nucleus, solid arrangement and capillary stroma. The cells express vimentin, inhibin, protein S-100, steroid hormones, calretinin and cytokeratin (focally) [32].

Approximately 10% of Leydig cell tumours are malignant and present with the following parameters [359, 360]:

- large size (> 5 cm);
- older age;
- increased mitotic activity (> 3 per 10 high-power field [HPF];

- vascular invasion;
- cytological atypia;
- increased MIB-1 expression;
- necrosis;
- infiltrative margins;
- extension beyond the testicular parenchyma;
- DNA aneuploidy.

9.2.3 **Diagnosis**

Patients either present with a painless enlarged testis or the tumour is found incidentally on US. In up to 80% of cases, hormonal disorders with high oestrogen and oestradiol levels, low testosterone, and increased levels of LH and FSH are reported [361, 362], while negative results are always obtained for the testicular germ cell tumour-markers AFP, hCG, LDH and PLAP. Up to 10% of adult patients present with gynaecomastia [362, 363]. Only 3% of tumours are bilateral [356].

Diagnostic work-up must include markers, hormones (at least testosterone, LH and FSH; if not conclusive, also oestrogen, oestradiol, progesterone and cortisol), US of both testes, and CT of chest and abdomen. On US, it may be possible to observe well-defined, small, hypoechoic lesions with hypervascularisation, however, the appearance is variable and is indistinguishable from germ-cell tumours [364]. The proportion of metastatic tumours in all published case reports is less than 10%. In three old series with long follow-up, 18 metastatic tumours were found in a total of 83 cases (21.7%) [356, 359, 365], while 5 recently published studies with long follow-up reported only 2 metastatic tumours in 156 patients (1.3%) [362, 363, 366-368].

9.3 **Sertoli cell tumours**

9.3.1 **Epidemiology**

Sertoli cell tumours account for fewer than 1% of testicular tumours, and the mean age at diagnosis is around 45 years, with rare cases under 20 years of age [369, 370]. On rare occasions, these tumours may develop in patients with androgen insensitivity syndrome and Peutz-Jeghers syndrome.

9.3.2 **Pathology of Sertoli cell tumours**

These tumours are well circumscribed, yellow, tan or white in colour, with an average diameter of 3.5 cm [369]. Microscopically, the cells are eosinophilic to pale with vacuolated cytoplasm. The nuclei are regular with grooves and inclusions may be present. The arrangement of the cells is tubular or solid; a cord-like or retiform pattern is possible. The stroma is fine with capillaries, but in some cases a sclerosing aspect predominates. The cells express vimentin, cytokeratins, inhibin (40%) and protein S-100 (30%) [369].

The rate of malignancy ranges between 10% and 22%. Signs of a malignant Sertoli tumour are as follows [371, 372]:

- large size (> 5 cm);
- increased mitotic activity (> 5 per 10 HPF);
- pleomorphic nuclei with nucleoli;
- necrosis;
- vascular invasion.

9.3.2.1 **Classification**

Three subtypes have been described [370]:

- Classic Sertoli cell tumour [369];
- Large cell calcifying form with characteristic calcifications [373, 374];
- Sclerosing form [375, 376].

9.3.3 **Diagnosis**

Patients present either with an enlarged testis or the tumour is found incidentally on US. Most classic Sertoli cell tumours are unilateral and unifocal. Hormonal disorders are infrequent, although gynaecomastia is sometimes seen [369]. The testicular tumour-markers AFP, hCG, LDH and PLAP are always negative.

Diagnostic work-up must include tumour markers, hormones (at least testosterone, LH and FSH; if not conclusive, also oestrogen, oestradiol, progesterone and cortisol), US of both testes and CT of chest and abdomen. Sertoli cell tumours are generally hypoechoic on US, but they can be of variant appearance and thus cannot be safely distinguished from germ-cell tumours [370]. Only the large cell calcifying form has a characteristic image with bright echogenic foci due to calcification [377].

Metastatic disease of 12% in classic Sertoli cell tumour has been reported. In general, affected patients are older, tumours are nearly always palpable, and show more than one sign of malignancy [369].

The **large cell calcifying** form is diagnosed in younger men and is associated with genetic dysplastic syndromes (Carney's complex [378] and Peutz-Jeghers syndrome [379] or, in about 40% of cases, endocrine disorders. 44% of cases are bilateral, either synchronous or metachronous, and 28% show multifocality with good prognosis [374].

Up to 20% of the large cell calcifying forms are malignant. It has been suggested that discrimination between an early and late onset type may define a different risk for metastatic disease (5.5% compared to 23%) [370].

The sclerosing subtype is very rare, unilateral, with a mean age around 40 years and metastases are infrequent [376].

9.4 Treatment of Leydig- and Sertoli cell tumours

Asymptomatic, small volume testicular tumours are often misinterpreted as germ-cell tumours, and inguinal orchidectomy is performed. An organ-sparing procedure in every small ultrasound-detected, nonpalpable intraparenchymal lesion is highly recommended in order to obtain a histological diagnosis. The incidence of benign definitive histology is high at approximately 80% [380]. In patients with symptoms of gynaecomastia or hormonal disorders, a non-germ-cell tumour should be considered and immediate orchidectomy avoided. In cases with germ-cell tumour in either frozen section or paraffin histology, orchidectomy is recommended as long as a contralateral normal testicle is present.

When diagnosed and treated early, long-term favourable outcomes are seen at follow-up in Leydig cell tumours, even with its potential metastatic behaviour. In stromal tumours with histological signs of malignancy, especially in older patients, orchidectomy and early retroperitoneal lymphadenectomy may be an option to prevent metastases [381] or to achieve long-term cure in stage IIa cases [382]. Prophylactic retroperitoneal lymph node dissection is unjustified for patients with clinical stage I disease without high-risk features [383].

Tumours that have metastasised to lymph nodes, lung, liver or bone respond poorly to chemotherapy or radiation and survival is poor [381]. No recommendations are available for the treatment of these patients.

9.5 Follow-up of Leydig- and Sertoli cell tumours

Without clinical signs of malignancy, an individualised surveillance strategy after orchidectomy is recommended in patients with one, or more, pathological features of malignancy. Follow-up is recommended in all high-risk patients; every 3 to 6 months with physical examination, hormone assays, scrotal and abdominal ultrasonography, chest radiography, and CT [362].

9.6 Granulosa cell tumour

This is a rare tumour with two variants: juvenile and adult. Less than 100 cases are reported with a predominance of the juvenile type.

- The juvenile type is benign. It is the most frequent congenital testicular tumour and represents about 1-5% of all prepubertal testicular neoplasms. The cystic appearance is characteristic of this tumour type [384, 385].
- The average age of the adult type at presentation is 45 years. The typical morphology is a homogeneous, yellow-grey tumour, with elongated cells with grooves in microfollicular and Call-Exner body arrangements [386].

Malignant tumours represent around 20% of cases. Lymphovascular invasion, necrosis, infiltrative borders and size > 4 cm may help in identifying cases with aggressive behaviour. Mitotic counts vary and do not appear to be of prognostic significance [387].

9.7 Thecoma/fibroma group of tumours

These tumours are rare with variable histology such as minimal invasion into surrounding testis, high cellularity, and increased mitotic rate. Their immunoprofile is variable and typically not diagnostic. They seem to be uniformly benign [388].

9.8 Other sex cord/gonadal stromal tumours

Sex cord/gonadal stromal tumours may be incompletely differentiated or in mixed forms.

There is limited experience with incompletely differentiated sex cord/gonadal stromal tumours and no reported

cases of metastasis [32]. In mixed tumour forms, all the histological components should be reported. However, the clinical behaviour most likely reflects the predominant pattern or the most aggressive component of the tumour [389].

9.9 Tumours containing germ cell and sex cord/gonadal stroma (gonadoblastoma)

Some patients with disorders of sex development (DSDs) have abnormal gonadal development with ambiguous genitalia and an increased risk of germ-cell tumours. If the arrangement of the germ cells is in a nested pattern and the rest of the tumour is composed of sex cord/gonadal stroma, the term gonadoblastoma is used. Bilateral tumours are present in 40% of cases. The prognosis correlates with the invasive growth of the germinal component [390, 391].

In the case of a diffuse arrangement of the different components, there are some doubts about the neoplastic nature of the germinal cells and some authors consider them to be entrapped rather than neoplastic [392].

9.10 Miscellaneous tumours of the testis

9.10.1 Tumours of ovarian epithelial types

These tumours resemble epithelial tumours of the ovary. A cystic appearance with occasional mucinous material can be observed. Microscopically, the aspect is identical to their ovarian counterparts, and their evolution is similar to that of the different epithelial ovarian subtypes. Some Brenner types are malignant [32].

9.10.2 Tumours of the collecting ducts and rete testis

These tumours are very rare. Benign (adenoma) and malignant (adenocarcinoma) have been reported, with malignant tumours showing local growth with a mortality rate of 40% within one year [393].

9.10.3 Tumours (benign and malignant) of non-specific stroma

These are very uncommon and have similar criteria, prognosis and treatment to soft tissue sarcomas.

9.		CONFLICT OF INTEREST	29

1. INTRODUCTION

The European Association of Urology (EAU) Guidelines on Penile Cancer provide up-to-date information on the diagnosis and management of penile squamous cell carcinoma (SCC). However, these Guidelines do not provide a standardised approach and the guidance and recommendations are provided without legal implications.

1.1 Panel composition

The EAU Penile Cancer Guidelines Panel consists of an international multidisciplinary group of clinicians, including a pathologist and an oncologist. Members of this panel have been selected based on their expertise and to represent the professionals treating patients suspected of harbouring penile cancer.

All experts involved in the production of this document have submitted potential conflict of interest statements.

1.2 Available publications

A quick reference document (Pocket guidelines) is available, both in print and in a number of versions for mobile devices. These are abridged versions which may require consultation together with the full text versions. Several scientific publications are available (the most recent paper dating back to 2014 [1] as are a number of translations of all versions of the Penile Cancer Guidelines. All documents are available free access through the EAU website Uroweb: <http://www.uroweb.org/guidelines/online-guidelines/>.

1.3 Publication history

The Penile Cancer Guidelines were first published in 2000 with the most recent full update achieved in 2014.

2. METHODS

2.1 Data identification

A systematic literature search on penile cancer was performed between August 2008 and November 2013. All articles relating to penile cancer ($n = 1602$) in the relevant literature databases were reviewed and 352 papers were considered suitable for adding to the research base of the Guidelines. A fully revised Guidelines was produced using the updated research base, together with several national and international guidelines on penile cancer (National Comprehensive Cancer Network [2], French Association of Urology [3] and the European Society of Medical Oncology [4]).

In this 2015 EAU Guidelines compilation, all standard information on levels of evidence (LE) and grading of recommendations (GR) has been taken out of the individual guidelines topics for the sake of brevity. This information is included in the introductory section of this print.

2.2 Review

This document was subjected to double-blind peer review prior to publication.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Definition of penile cancer

Penile carcinoma is usually a squamous cell carcinoma (SCC), although there are other types of penile cancer (see Table 3.3). Penile SCC usually arises from the epithelium of the inner prepuce or the glans. Penile SCC exists in several histological subtypes. Its pathology is similar to SCC of the oropharynx, female genitalia (cervix, vagina and vulva) and anus and shares some of the natural history.

3.2 Epidemiology

In the Western World, primary penile cancer is uncommon, with an overall incidence of $< 1.00/100,000$ males in Europe and the USA [5, 6], although there are several geographical areas in Europe with an incidence over

1.00/100,000 (Figure 3.1) [7]. In North America [5], the incidence of penile cancer is also affected by race and ethnicity, with the incidence highest in white Hispanics (1.01/100,000) compared to Alaskan, Native American Indians (0.77 /100,000), blacks (0.62/100,000) and white non-Hispanics (0.51/100,000), respectively. In contrast, other parts of the world, such as South America, South East Asia and parts of Africa, have a much higher incidence, representing up to 1-2% [7] of malignant diseases in men in some countries.

Penile cancer is common in regions with a high prevalence of human papilloma virus (HPV) [5]. The annual age-adjusted incidence is 0.7-3.0/100,000 men in India, 8.3/100,000 men in Brazil and even higher in Uganda, where it is the most commonly diagnosed male cancer [7, 8]. Much knowledge about penile cancer comes from countries with a high incidence.

The incidence of penile cancer is related to the prevalence of HPV in the population, which may account for the variation in incidence as the worldwide HPV prevalence varies considerably. There is also a less noticeable variation in incidence between European regions (Figure 3.1). At least one third of cases can be attributed to HPV-related carcinogenesis. There are no data linking penile cancer to HIV or AIDS.

In the USA, the overall age-adjusted incidence rate decreased from 1973 to 2002 from 0.84/100,000 in 1973-1982 to 0.69/100,000 in 1983-1992, and to 0.58/100,000 in 1993-2002 [5]. In Europe, the overall incidence has been stable from the 1980s until today [6], with an increased incidence reported in Denmark [9] and the UK. A UK longitudinal study confirmed a 21% increase in incidence during 1979-2009 [10]. The incidence of penile cancer increases with age [6]. The peak age is during the sixth decade of life, though the disease does occur in younger men [11].

Figure 3.1: Annual incidence rate (world standardised) by European region/country*

*Adapted from [7].

3.3 Risk factors and prevention

Review of the published literature from 1966-2000 identified several risk factors for penile cancer [12] (Table 3.1) (LE: 2a).

Table 3.1: Recognised aetiological and epidemiological risk factors for penile cancer

Risk factors	Relevance	Ref
Phimosis	OR 11-16 vs. no phimosis	[13, 14]
Chronic penile inflammation (balanoposthitis related to phimosis) Balanitis xerotica obliterans (lichen sclerosus)	Risk	[15]
Sporalene and UVA phototherapy for various dermatological conditions such as psoriasis	Incidence rate ratio 9.51 with > 250 treatments	[16]
Smoking	5-fold increased risk (95% CI: 2.0-10.1) vs. non-smokers	[13, 14, 17]
HPV infection condylomata acuminata	22.4% in verrucous SCC 36-66.3% in basaloid-warty	[5, 18]
Rural areas, low socioeconomic status, unmarried		[19-22]
Multiple sexual partners, early age of first intercourse	3-5-fold increased risk of penile cancer	[12, 14, 23]

HPV = human papilloma virus; OR = odds ratio; SCC = squamous cell carcinoma; UVA = ultraviolet A.

Human papilloma virus infection (HPV) is an important risk factor; HPV DNA was found in 70-100% of intraepithelial neoplasia and in 30-40% of invasive penile cancer tissue samples (LE: 2a). It is thought to be a cofactor in the carcinogenesis of some variants of penile SCC [18] through interaction with oncogenes and tumour suppressor genes (P53, Rb genes) [24]. The commonest HPV subtypes in penile cancer are types 16 and 18 [25] and the risk of penile cancer is increased in patients with condyloma acuminata [26] (LE: 2b). The incidence of penile cancer is higher in regions with high HPV prevalence.

It remains unclear whether HPV-associated penile cancer has a different prognosis to non-HPV-associated penile cancer. A significantly better 5-year disease-specific survival was reported for HPV-positive versus HPV-negative cases (93% vs. 78%) [27], while others reported no difference in lymph node metastases and a 10-year survival rate [28].

There is no direct association between the incidence of penile cancer and cervical cancer. However, both cancers are independently linked with the prevalence of HPV infections [29, 30]. Female sexual partners of patients with penile cancer do not have an increased incidence of cervical cancer. There is no current recommendation for HPV vaccination in boys because of a different HPV-associated risk pattern in penile and anal cancer. The epidemiological effects of HPV vaccination in girls are also awaited [31, 32].

Phimosis is strongly associated with invasive penile cancer [14, 19, 33, 34], probably due to associated chronic infection since smegma is not a carcinogen [33]. A further risk factor suggested by epidemiological studies is cigarette smoking (4.5-fold increased risk (95% CI: 2.0-10.1) [34]. The incidence of lichen sclerosus (balanitis xerotica obliterans) in patients with penile cancer is relatively high but is not associated with increased rates of adverse histopathological features, including carcinoma *in situ* (CIS). Other epidemiological risk factors are a low levels of socioeconomic status and education [19].

Countries and cultures practising routine neonatal circumcision have a lower incidence of penile cancer. Israeli Jews have the lowest incidence at 0.3 per 100,000/year. However, neonatal circumcision removes about half the tissue that can develop into penile cancer. A US study of 100 matched case-control pairs found that the protective effect of neonatal circumcision against invasive penile cancer (OR 0.41) became much weaker when the comparative analysis was only against men without a history of phimosis (OR 0.79, 95% CI: 0.29-2 [14]). Neonatal circumcision does not reduce the risk of CIS [14].

3.4 Pathology

Squamous cell carcinoma accounts for > 95% of cases of penile malignancies (Tables 3.2 and 3.3). It is not known how often SCC is preceded by premalignant lesions (Table 3.2) [35-38]. Some variants of primary penile cancer have not yet been included in the WHO classification, including pseudohyperplastic carcinoma, carcinoma cuniculatum, pseudoglandular carcinoma, and warty-basaloid carcinoma.

There are many mixed forms of SCC, including the warty-basaloid form (50-60% of mixed penile SCC), usual- verrucous (hybrid), usual-warty, usual-basaloid or usual-papillary and other rarer combinations.

Other penile malignant lesions include melanocytic lesions, mesenchymal tumours, lymphomas and metastases. These are unrelated to penile cancer and rarer. Aggressive penile sarcoma has been reported. Penile metastases from other neoplasias often have a prostatic or colorectal origin.

Table 3.2: Premalignant penile lesions (precursor lesions)

Lesions sporadically associated with SCC of the penis
• Cutaneous horn of the penis
• Bowenoid papulosis of the penis
• Lichen sclerosus (balanitis xerotica obliterans)
Premalignant lesions (up to one-third transform to invasive SCC)
• Intraepithelial neoplasia grade III
• Giant condylomata (Buschke-Löwenstein)
• Erythroplasia of Queyrat
• Bowen's disease
• Paget's disease (intradermal ADK)

Table 3.3: Histological subtypes of penile carcinomas, their frequency and outcome

Subtype	Frequency (% of cases)	Prognosis
Common SCC	48-65	Depends on location, stage and grade
Basaloid carcinoma	4-10	Poor prognosis, frequently early inguinal nodal metastasis [39]
Warty carcinoma	7-10	Good prognosis, metastasis rare
Verrucous carcinoma	3-8	Good prognosis, no metastasis
Papillary carcinoma	5-15	Good prognosis, metastasis rare
Sarcomatoid carcinoma	1-3	Very poor prognosis, early vascular metastasis
Mixed carcinoma	9-10	Heterogeneous group
*Pseudohyperplastic carcinoma	< 1	Foreskin, related to lichen sclerosus, good prognosis, metastasis not reported
Carcinoma cuniculatum	< 1	Variant of verrucous carcinoma, good prognosis, metastasis not reported
Pseudoglandular carcinoma	< 1	High-grade carcinoma, early metastasis, poor prognosis
Warty-basaloid carcinoma	9-14	Poor prognosis, high metastatic potential [40] (higher than in warty, lower than in basaloid SCC)
Adenosquamous carcinoma	< 1	Central and peri-meatal glans, high-grade carcinoma, high metastatic potential but low mortality
Mucoepidermoid carcinoma	< 1	Highly aggressive, poor prognosis
Clear cell variant of penile carcinoma	1-2	Exceedingly rare, associated with HPV, aggressive, early metastasis, poor prognosis, outcome is lesion-dependent, frequent lymphatic metastasis [41]

3.4.1 Gross handling

Tissue sections must completely include small lesions and at least 3-4 blocks of bigger lesions. Lymph nodes must be totally included to ensure the detection of micrometastases. Surgical margins must be completely included.

3.4.2 Pathology report

The pathology report must include the anatomical site of the primary tumour, the histological type/subtypes, grade, perineural invasion, depth of invasion, vascular invasion (venous/lymphatic), irregular growth and front of invasion, urethral invasion, invasion of corpus spongiosum/cavernosum and surgical margins.

3.4.3 Grading

The TNM classification for penile cancer includes tumour grade because of its prognostic relevance (Table 4.1). Both Broder's classification and the WHO grading system for grading penile cancer are highly dependent on the observer and are no longer used [42].

3.4.4 Pathological prognostic factors

Carcinomas limited to the foreskin have a better prognosis and lower risk of regional metastasis [43]. Perineural invasion and histological grade are very strong predictors of a poor prognosis and cancer-specific mortality [44]. Although tumour grade is a predictor of metastatic spread, it can be difficult to grade heterogeneous

tumours. Lymphatic invasion is an independent predictor of metastasis. Venous embolism is often seen in advanced stages.

Types of penile SCC with an excellent prognosis include: verrucous, papillary, warty, pseudohyperplastic and carcinoma cuniculatum. These SCCs are locally destructive, rarely metastasize and have a very low cancer-related mortality.

High-risk SCC variants are the basaloid, sarcomatoid, adenosquamous and poorly differentiated types. They metastasize early and mortality is high. An intermediate-risk SCC group comprises the usual SCC, mixed forms and the pleomorphic form of warty carcinomas.

Stage pT3 tumours that invade the distal (glandular) urethra (25% of cases) do not have a worse outcome [45]. However, invasion of the more proximal urethra, also classified as stage pT3, is due to a highly aggressive SCC with a poor prognosis (see Table 3.3).

The inclusion in the same pT2 group of invasion of the corpus spongiosum and of the corpora cavernosa is confusing clinically because these conditions have very different prognoses. After a mean follow-up of 3 years, higher rates of local recurrence (35% vs. 17%) and mortality (30% vs. 21%) were reported in pT2 tumours (n = 72) with tunica or cavernosal involvement versus glans-only invasion, respectively [46] (LE: 2b). The authors proposed defining T2a with spongiosum-only invasion and T2b with tunica and/or corpus cavernosum invasion. A similar prognostic difference was observed in a retrospective analysis of 513 patients treated between 1956 and 2006 [47].

Long-term survival is similar in patients with T2 and T3 tumours and in patients with N1 and N2 disease, using the 1987-2002 TNM classification [47] (LE: 2a).

Two nomograms, based only on small numbers, were developed to estimate prognosis in penile cancer. One study suggested that pT1G1 tumours are low-risk tumours, with 0% developing lymph node metastases, in contrast to high-risk pT2/3 G2/3 tumours, with 83% developing lymph node metastases [48].

Remaining tumours were intermediate-risk tumours with 33% developing metastases. Another study reported similar findings and recommended prophylactic lymphadenectomy for high-risk patients [49]. There is also a 'prognostic index', which ranks several pathological parameters (grade, deepest anatomical level, perineural invasion) to predict the likelihood of inguinal lymph node metastases and 5-year survival [50]. The lower the score, the higher is the probability of 95% survival at 5 years.

3.4.5 **Penile cancer and HPV**

A high prevalence of HPV infection is found in basaloid (76%), mixed warty-basaloid (82%) and warty penile SCCs (39%). The commonest HPV-types in penile SCC are HPV 16 (72%), HPV 6 (9%) and HPV 18 (6%). Verrucous and papillary penile SCCs are HPV-negative. Overall, only one-third of penile SCCs show HPV infection, but those that do are usually infected by several HPV strains.

3.4.6 **Molecular biology**

Little is known about the role of chromosomal abnormalities in penile SCC in biological behaviour and patient outcome [24]. Lower DNA copy and alteration numbers are linked to poorer survival. Alterations in the locus 8q24 may play a major role and are implicated in other neoplasms such as prostate cancer [51, 52]. Telomerase activity has been shown in invasive penile carcinoma [53], and some authors have shown that aneuploidy changed according to tumour grade [54].

Epigenetic alterations evaluating the methylation pattern of CpG islands in CDKN2A have been described. CDKN2A encodes for two tumour suppressor proteins (p16INK4A and p14ARF) which control cell growth through Rb and p53 pathways. Poetsch et al. showed that 62% of invasive SCC of the penis displayed allelic loss of p16 and 42% promoter hypermethylation. Tumours immunohistochemically negative for p16 showed hypermethylation of and/or LOH near the p16INK4A locus. In that study, p16 negativity was linked to lymph node metastasis, in another study to prognosis [55]. Allelic loss of the p53 gene is a frequent event in penile SCC (42%) [56] and p53 expression has been linked to poor prognosis [57]. Another element influencing lymph node metastasis is the metastasis suppressor protein KAI1/CD82; decreased expression of this protein favours lymph node metastasis [58].

3.4.7 **Penile biopsy**

The diagnosis of penile cancer must be confirmed by biopsy. Although penile cancer is usually obvious, very occasionally it may be confused with non-SCC penile carcinoma or inflammatory lesions.

Histological confirmation is necessary to guide management:

- when there is doubt about the exact nature of the lesion (e.g. CIS, metastasis or melanoma) and/or;
- treatment is planned with topical agents, radiotherapy or laser surgery;
- lymph node treatment is based on pre-operative histological information (risk-adapted strategy).

Biopsy size is important. In biopsies with an average size of 0.1 cm, it was difficult to evaluate the depth of invasion in 91% of biopsies. There was also discordance between the grade at biopsy and in the final

specimen in 30% of cases and failure to detect cancer in 3.5% of cases [35]. Also, vascular and lymphatic tumour emboli were detected in only 9-11% of cases. Although a punch biopsy may be sufficient for superficial lesions, an excisional biopsy is preferred because it should be deep enough to assess properly the degree of invasion and stage.

3.4.8 *Intra-operative frozen sections and surgical margins*

The aim of surgical treatment is complete removal of the penile carcinoma and negative surgical margins. The width of negative surgical margins should follow a risk-adapted strategy based on tumour grade. Negative surgical margins may be confirmed intra-operatively by frozen section [59]. If surgical margins are studied following these criteria (including urethral and periurethral tissue), only 5 mm of tumour-free tissue is sufficient to consider the surgical margins to be negative [60].

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 TNM classification

The 2009 TNM classification [61] stratifies the T1 category into two prognostically different risk groups, depending on the presence or absence of lymphovascular invasion and grading (Table 4.1). The rationale for a potential further subdivision of the T2 category is discussed under Section 3.4.4 [46, 47].

The 2009 TNM classification recognizes the adverse effect of extracapsular spread on prognosis and therefore classifies any inguinal lymph node metastasis with extracapsular extension as pN3 [61]. Retroperitoneal lymph node metastases are extraregional nodal and therefore distant metastases.

Table 4.1: 2009 TNM clinical and pathological classification of penile cancer [61]

Clinical classification	
T - Primary Tumour	
TX	Primary tumour cannot be assessed
T0	No evidence of primary tumour
Tis	Carcinoma <i>in situ</i>
Ta	Non-invasive carcinoma
T1	Tumour invades subepithelial connective tissue
T1a	Tumour invades subepithelial connective tissue without lymphovascular invasion and is not poorly differentiated or undifferentiated (T1G1-2)
T1b	Tumour invades subepithelial connective tissue with lymphovascular invasion or is poorly differentiated or undifferentiated (T1G3-4)
T2	Tumour invades corpus spongiosum and/or corpora cavernosa
T3	Tumour invades urethra
T4	Tumour invades other adjacent structures
N - Regional Lymph Nodes	
NX	Regional lymph nodes cannot be assessed
N0	No palpable or visibly enlarged inguinal lymph node
N1	Palpable mobile unilateral inguinal lymph node
N2	Palpable mobile multiple unilateral or bilateral inguinal lymph nodes
N3	Fixed inguinal nodal mass or pelvic lymphadenopathy, unilateral or bilateral
M - Distant Metastasis	
M0	No distant metastasis
M1	Distant metastasis
Pathological classification	
The pT categories correspond to the clinical T categories. The pN categories are based upon biopsy or surgical excision	
pN - Regional Lymph Nodes	
pNX	Regional lymph nodes cannot be assessed
pN0	No regional lymph node metastasis
pN1	Intranodal metastasis in a single inguinal lymph node
pN2	Metastasis in multiple or bilateral inguinal lymph nodes
pN3	Metastasis in pelvic lymph node(s), unilateral or bilateral or extranodal extension of any regional lymph node metastasis
pM - Distant Metastasis	
pM0	No distant metastasis
pM1	Distant metastasis
G - Histopathological Grading	
GX	Grade of differentiation cannot be assessed
G1	Well differentiated
G2	Moderately differentiated
G3-4	Poorly differentiated/undifferentiated

5. DIAGNOSTIC EVALUATION AND STAGING

Penile cancer can be cured in over 80% of cases if diagnosed early. Local treatment, although potentially life-saving, can be mutilating and devastating for the patient's psychological well-being.

5.1 Primary lesion

Penile carcinoma is usually a clinically obvious lesion. However, it may be hidden under a phimosis. Physical examination should include palpation of the penis to assess the extent of local invasion. Ultrasound (US) can give information about infiltration of the corpora [62, 63]. Magnetic resonance imaging (MRI) with an artificially induced erection can help to exclude tumour invasion of the corpora cavernosa if preservation of the penis is planned [64, 65].

5.2 Regional lymph nodes

Careful palpation of both groins for enlarged inguinal lymph nodes must be part of the initial physical examination of patients with penile cancer.

5.2.1 Non-palpable inguinal nodes

If there are no palpable lymph nodes, the likelihood of micrometastatic disease is about 25%. Imaging studies are not helpful in staging clinically normal inguinal regions, though imaging may be helpful in obese patients in whom palpation is unreliable or impossible:

- Inguinal US (7.5 MHz) can reveal abnormal nodes with some enlargement. The longitudinal/transverse diameter ratio and absence of the lymph node hilum are findings with relatively high specificity [66];
- Conventional CT or MRI scans cannot detect micrometastases reliably [67];
- Imaging with ¹⁸FDG-positron emission tomography (PET)/CT does not detect lymph node metastases < 10 mm [68, 69].

The further diagnostic management of patients with normal inguinal nodes should be guided by pathological risk factors. Lymphovascular invasion, local stage and grade are risk factors for the likelihood of lymphatic metastasis [70, 71]. Nomograms are not accurate enough. Invasive lymph node staging is required in patients at intermediate- or high-risk of lymphatic spread (see Section 6.2).

5.2.2 Palpable inguinal nodes

Palpable lymph nodes are highly suspicious for lymph node metastases. Physical examination should note the number of palpable nodes on each side and whether these are fixed or mobile. Additional inguinal imaging does not alter management (see Section 6) and is usually not required.

A pelvic CT scan can be used to assess the pelvic lymph nodes. Imaging with ¹⁸FDG-PET/CT has reported a high sensitivity of 88-100%, with a specificity of 98-100%, for confirming metastatic nodes in patients with palpable inguinal lymph nodes [69, 72].

5.3 Distant metastases

An assessment of distant metastases should be performed in patients with positive inguinal nodes [73-75] (LE: 2b). Computed tomography of the abdomen and pelvis and a chest X-ray are recommended. Thoracic CT is more sensitive than chest X-ray. PET/CT is an option for identifying pelvic nodal and distant metastases in patients with positive inguinal nodes [76].

There is no established tumour marker for penile cancer. The SCC antigen (SCC Ag) is increased in < 25% of penile cancer patients. One study found that SCC Ag did not predict occult metastatic disease, but was an indicator of disease-free survival in lymph-node-positive patients [77].

5.4 Guidelines for the diagnosis and staging of penile cancer

	GR
Primary tumour	
Physical examination, recording morphology, extent and invasion of penile structures.	C
MRI with artificial erection in selected cases with intended organ-preserving surgery.	
Inguinal lymph nodes	
Physical examination of both groins, recording number, laterality and characteristics of inguinal nodes: <ul style="list-style-type: none">• If nodes are not palpable, invasive lymph node staging in high-risk patients (see Section 6).• If nodes are palpable, a pelvic CT may be indicated, PET/CT is an option.	C
Distant metastases	
In N+ patients, an abdominopelvic CT scan and chest X-ray are required for systemic staging.	C
PET/CT scan is an option.	
In patients with systemic disease or with relevant symptoms, a bone scan may be indicated.	

CT = computed tomography; PET = positron emission tomography.

6. DISEASE MANAGEMENT

6.1 Treatment of the primary tumour

Treatment of the primary penile cancer lesion aims to remove the tumour completely, while preserving as much of the penis as possible without compromising radicality. Local recurrence has little effect on long-term survival so that organ preservation strategies can be used [78].

The overall quality of available research evidence is low. There are no randomised controlled trials or observational studies for surgical management of localised penile cancer nor studies comparing surgical and non-surgical modalities. The available studies are often biased.

However, penile preservation appears to be superior in functional and cosmetic outcomes. It is the primary treatment method for men with localised penile cancer. However, there are no randomised studies comparing organ-preserving and ablative treatment strategies, only retrospective studies with a level of evidence of 3 or less.

Histological diagnosis with local staging must be obtained in all cases, especially if considering non-surgical treatment modalities (GR: C).

Treatment of the primary tumour and of the regional nodes can be staged. It is mandatory to remove all malignant tissue with negative surgical margins. Patients must be counselled about all relevant treatment modalities.

Local treatment modalities for small and localised penile cancer include excisional surgery, external beam radiotherapy, brachytherapy and laser ablation.

6.1.1 Treatment of superficial non-invasive disease (CIS)

For penile CIS, topical chemotherapy with imiquimod or 5-fluorouracil (5-FU) can be an effective first-line treatment. They have relatively low toxicity and adverse events, but efficacy is limited. Complete responses have been reported in up to 57% of CIS cases [79]. For the reason of a high-rate of persistence and/or recurrence, close and long-term surveillance of such patients is required. If topical treatment fails, it should not be repeated.

Laser treatment can be used for CIS. Photodynamic control may be used in conjunction with CO₂ laser treatment [80].

Alternatively, total or partial glans resurfacing can be offered as a primary treatment modality for CIS and as a secondary treatment in case of treatment failure with topical chemotherapy or laser therapy. Glans resurfacing is a surgical technique which consists of complete abrasion of the glandular epithelium with covering by a split skin graft. With glans resurfacing for presumed non-invasive disease, up to 20% of patients are found to have superficial invasive disease [81].

6.1.2 Treatment of invasive disease confined to the glans (category Ta/T1a)

A penis-preserving strategy is recommended (GR: C) for small and localised invasive lesions (Ta/T1a).

It is mandatory to do a biopsy to confirm diagnosis prior to using conservative treatments (GR: C). All patients must be circumcised before considering conservative non-surgical treatments. For tumours confined to the prepuce, radical circumcision alone may be curative provided that negative surgical margins are confirmed by definitive histology.

For all surgical treatment options, the intraoperative assessment of surgical margins by frozen section is recommended (GR: C) because tumour-positive margins lead to local recurrence [82]. Total removal of the glans (glansectomy) and prepuce has the lowest recurrence rate of the treatments for small penile lesions (2%) [82]. Negative surgical margins are imperative when using penile-conserving treatments (GR: C) and a margin of 5 mm is considered oncologically safe [82, 83].

Treatment choice should depend on tumour size, histology, including stage and grade, localisation (especially relative to the meatus) and patient preference as there are no documented differences in long-term local recurrence rates between surgery, laser and radiation therapy.

6.1.3 Results of different surgical organ-preserving treatments

There are only retrospective case series for these treatments. The results have been reported heterogeneously so that the database for assessment is of limited quality. There have been no randomised trials.

6.1.3.1 Laser therapy

Laser ablation is carried out with a Nd:YAG laser or a CO₂ laser [84-89]. Visualization may be improved by photodynamic diagnosis.

The results of CO₂ laser treatment have been reported by three studies all from the same institution [84-86]. Laser treatment was given in combination with radiotherapy or chemotherapy and patients included had CIS or T1 penile cancers. Follow-up was 5 years (median) in all three studies. There is some overlap

between the cohorts reported, with a total of 195 patients included in these retrospective series.

No cancer-specific deaths were reported. One study reported an estimated cumulative risk of local recurrence at 5 years of 10% with CIS (n = 106) and 16% with T1 tumour (n = 78) [84]. In all three series taken together, local recurrence ranged from 14% for CIS and T1 tumours [86] to 23% for T1 tumours [85]. The reported rate of inguinal nodal recurrence after local CO₂ laser treatment was 0% (0/11) [86] and 4% (2/56) [85]. Secondary partial penectomy at 10 years was 3% and 10%, depending on the tumour (CIS vs. T1) and whether combination treatment had been given or not [84].

The four studies on the results of Nd:YAG laser treatment [87-90] together report a total of 150 patients with a follow-up of at least 4 years. Local recurrence rates at last follow-up ranged across the four studies from 10% (3/29) [87] to 48% (21/44) [88]. In one study [89], recurrence-free survival rates were reported as 100%, 95% and 89% at 1, 2 and 5 years. Inguinal nodal recurrence were reported in 21% (9/44) [87]. Cancer-related deaths were reported in 2% (1/54) [90] and 9% of patients (4/44) [88], respectively. Three studies from the same institution, probably including overlapping patient cohorts reported overall survival by censored or uncensored data which ranged from 100% at 4 years [87] and 95% [89] to 85% [91] at 7 years. The rate of secondary partial penectomy after initial Nd:YAG laser treatment was reported as 4% (1/23) [89] and 45% (20/44) [88], respectively. Complications, urinary- and sexual function outcomes were reported by only one study with 29 patients [87], which reported no complications and no change in urinary and sexual function after successful Nd:YAG laser treatment.

Other studies have reported data on a variety of laser treatments with either CO₂ laser, Nd:YAG laser, a combination of both, or a KTP laser [92-95], with a mean follow-up of 32-60 months and stages CIS up to T3 included. The four studies reported on a total of 138 patients.

The cancer-specific survival probability at 5 years was 95% in one study using the Kaplan-Meier method [93]. This was consistent with the finding from another study in which the cancer-specific mortality rate was relatively low at 2% (1/44) at a mean follow-up of around 5 years [94]. Local recurrence rates were 11% (5/44) [94], 19% (13/67) [93] and 26% (5/19) [95]. In one study recurrence-free survival at 5 years was estimated to be 88% [93].

6.1.3.2 *Moh's micrographic surgery*

Moh's micrographic surgery is a technique by which histological margins are taken in a geometrical fashion around a cone of excision. This technique has not been widely used. Only two studies reported a total of 66 patients [96, 97]. The original description [96] consisted of 33 consecutive patients treated between 1936 and 1986 and reported on 29 patients with at least 5 years' follow-up. In each study there was one secondary penile amputation and one death from penile cancer. In Mohs series, 79% (23/29) were cured at 5 years [96]. In the other series, 68% (17/25) were recurrence-free after a median of 37 months and 8% (2/25) had inguinal nodal recurrence and died of the disease [97]. One cancer-specific death was reported in each series, with the local recurrence rate was 32% (8/25) in one series [97].

6.1.3.3 *Glans resurfacing*

Three studies have reported results with glans resurfacing [81, 98, 99] in a total of 71 patients with CIS or T1. The range of the median duration of follow-up in the three studies was 21-30 months. No cancer-specific deaths were reported, the rates of local recurrence were 0% (0/10) [98] and 6% (2/33) [99], without reports of nodal recurrence. There were no reported complications.

6.1.3.4 *Glansectomy*

Results of another fairly new technique, glansectomy, were reported by three studies [82, 100, 101], while another study also reported on glans-preserving surgery [101]. A total of 68 patients with a follow-up of 114 months [100] and 63 months [101] were included. One patient (8%) had a local recurrence [100] and six patients (9%) had inguinal nodal metastases. No cancer-specific deaths were reported. Another group reported 87 patients with six local (6.9%), 11 regional (12.6%) and two systemic recurrences (2.3%), during a mean follow-up of 42 months [82].

6.1.3.5 *Partial penectomy*

Results of partial penectomy were reported in eight rather heterogeneous studies [86, 101-107] amounting to 184 included patients, with T1-T3 tumours, and follow-up from 40-194 months. 0-27% of patients died of penile cancer, with local recurrence rates ranging from 4-50% of patients. The 5-year overall survival rate was reported by three studies and ranged from 59-89% [104, 105, 107].

6.1.3.6 *Summary of results of surgical techniques*

There is not sufficient evidence to suggest a difference regarding the outcomes of different penis-sparing strategies, which generally appear to show good oncological outcomes. Although conservative surgery may

improve quality of life, local recurrence is more likely than after radical surgery, e.g. partial penectomy (5-12% vs. 5%). In a large cohort of patients undergoing conservative surgery, isolated local recurrence was 8.9%, with a 5-year disease-specific survival rate of 91.7%. Tumour grade, stage and lymphovascular invasion appear to be predictors of local recurrence.

6.1.4 Results of radiotherapy for T1 and T2 disease

Radiation treatment of the primary tumour is an alternative organ-preserving approach with good results in selected patients with T1-2 lesions < 4 cm in diameter [108-113] (LE: 2b). External radiotherapy is given with a minimum dose of 60 Gy combined with a brachytherapy boost or brachytherapy on its own [109, 111]. Radiotherapy results are best with penile brachytherapy with local control rates ranging from 70-90% [109, 111]. The American Brachytherapy Society and the Groupe Européen de Curiethérapie-European Society of Therapeutic Radiation Oncology (ABS-GEC-ESTRO) consensus statement for penile brachytherapy reported good tumour control rates, acceptable morbidity and functional organ preservation for penile brachytherapy for T1 and T2 penile cancers [114]. The rates of local recurrence after radiotherapy are higher than after partial penectomy. With local failure after radiotherapy, salvage surgery can achieve local control [115]. Patients with lesions > 4 cm are not candidates for brachytherapy.

Common complications with radiotherapy include urethral stenosis (20-35%), glans necrosis (10-20%) and late fibrosis of the corpora cavernosa [116] (LE: 3). With brachytherapy, meatal stenosis occurs in > 40% of cases.

Table 6.1: Summary of reported complications and oncological outcomes of local treatments*

Treatment	Complications	Local recurrence	Nodal recurrence	Cancer-specific deaths	References
Nd:YAG laser	None reported	10-48%	21%	2-9%	[87-90]
CO ₂ -laser	Bleeding, meatal stenosis (both < 1%)	14-23%	2-4%	None reported	[84-86]
Lasers (unspecified)	Bleeding (8%), local infection 2%	11-26%	2%	2-3%	[92-95]
Moh's micrographic surgery	Local infection 3%, Meatal stenosis 6%	32%	8%	3-4%	[96, 97]
Glans resurfacing	None reported	4-6%	Not reported	Not reported	[81, 98, 99]
Glansectomy	None reported	8%	9%	None reported	[100, 101]
Partial penectomy	Not reported	4-13%	14-19%	11-27%	[86, 104, 105, 107]
Brachytherapy	Meatal stenosis > 40%	10-30%	Not reported	Not reported	[108, 109, 111]
Radiotherapy	Urethral stenosis 20-35%, Glans necrosis 10-20%	Not reported	Not reported	Not reported	[110, 113-116]

*The ranges are the lowest and highest number of occurrences reported in different series.

6.1.5 Summary of treatment recommendations for non-invasive and localised superficially invasive penile cancer

6.1.5.1 Treatment of invasive disease confined to the corpus spongiosum/glans (Category T2)

Total glansectomy, with or without resurfacing of the corporeal heads, is recommended [102] (LE: 3; GR: C). Radiotherapy is an option (see Section 6.1.6). Partial amputation should be considered in patients unfit for reconstructive surgery [115] (GR: C).

6.1.5.2 Treatment of disease invading the corpora cavernosa and/or urethra (category T2/T3)

Partial amputation with a tumour-free margin with reconstruction is standard [112] (GR: C). A surgical margin of 5 mm is considered safe [82, 83]. Patients should remain under close follow-up. Radiotherapy is an option.

6.1.5.3 Treatment of locally advanced disease invading adjacent structures (category T3/T4)

These are relatively rare (Europe 5%, Brazil 13%) [83]. Total penectomy with perineal urethrostomy is standard surgical treatment for T3 tumours [83] (GR: C).

In more advanced disease (T4), neoadjuvant chemotherapy may be advisable, followed by surgery in responders, as in the treatment of patients with fixed enlarged inguinal nodes (see Section 6.2.4) (GR: C). Otherwise, adjuvant chemotherapy or palliative radiotherapy are options (GR: C; see Sections 6.2.4 and 6.1.6).

6.1.5.4 Local recurrence after organ-conserving surgery

A second organ-conserving procedure can be performed if there is no corpus cavernosum invasion [60, 80, 83, 112] (GR: C). For large or high-stage recurrence, partial or total amputation is required [116] (GR: C). A total phallic reconstruction may be offered to patients undergoing total/subtotal amputation [117, 118].

6.1.6 Guidelines for stage-dependent local treatment of penile carcinoma

Primary tumour	Organ-preserving treatment whenever possible	LE	GR
Tis	Topical treatment with 5-fluorouracil or imiquimod for superficial lesions with or without photodynamic control.	3	C
	Laser ablation with CO ₂ or Nd:YAG laser.		
	Glans resurfacing.		
Ta, T1a (G1, G2)	Wide local excision with circumcision CO ₂ or Nd:YAG laser surgery with circumcision.	3	C
	Laser ablation with CO ₂ or Nd:YAG laser.		
	Glans resurfacing.		
	Glansectomy with reconstructive surgery, with or without skin grafting.		
	Radiotherapy by external beam or as brachytherapy for lesions < 4 cm.		
T1b (G3) and T2 confined to the glans	Wide local excision plus reconstructive surgery, with or without skin grafting.	3	C
	Laser ablation with circumcision.		
	Glansectomy with circumcision, with reconstruction.		
	Radiotherapy by external beam or brachytherapy for lesions < 4 cm in diameter.		
T2 with invasion of the corpora cavernosa	Partial amputation and reconstruction.	3	C
	Radiotherapy by external beam or brachytherapy for lesions < 4 cm in diameter.		
T3 with invasion of the urethra	Partial penectomy or total penectomy with perineal urethrostomy.	3	C
T4 with invasion of other adjacent structures	Neoadjuvant chemotherapy followed by surgery in responders. Alternative: palliative external beam radiation.	3	C
Local recurrence after conservative treatment	Salvage surgery with penis-sparing treatment in small recurrences or partial amputation.	3	C
	Large or high-stage recurrence: partial or total amputation.	3	C

CO₂ = carbon dioxide; Nd:YAG = neodymium:yttrium-aluminium-garnet.

6.2 Management of regional lymph nodes

The development of lymphatic metastases in penile cancer follows the route of anatomical drainage. Inguinal and pelvic lymph nodes provide the regional drainage system for the penis, and the superficial and deep inguinal lymph nodes are the first regional nodal group to manifest lymphatic metastatic spread, which can be unilateral or bilateral [78].

All inguinal sentinel nodes appear to be located in the superior and central inguinal zones, with most in the medial superior zone [79]. No lymphatic drainage was observed from the penis to the two inferior regions of the groin and no direct drainage to the pelvic nodes was visualised. These findings confirm earlier studies [80, 81].

The second regional lymph node groups are the ipsilateral pelvic lymph nodes. Pelvic nodal disease does not seem to occur without ipsilateral inguinal lymph node metastasis and there are no reports of crossover metastatic spread from one inguinal side to the other pelvic side. Further metastatic lymph node spread from the pelvic nodes to para-aortic and paracaval nodes is outside the regional lymph node drainage system of the penis and is classified as systemic metastatic disease.

The management of regional lymph nodes is decisive for long-term patient survival. Cure can be achieved in metastatic disease confined to the regional lymph nodes. Lymphadenectomy is the treatment of choice for inguinal lymph node metastases (GR: B). Multimodal treatment combining surgery and polychemotherapy is often indicated.

Management of regional lymph nodes is stage-dependent. In clinically node-negative patients (cN0), micrometastatic disease occurs in about 25% of cases and is related to the local tumour stage and grade. In clinically positive lymph nodes (cN1/cN2), metastatic disease is highly likely and no time should be wasted on antibiotic treatment. Enlarged fixed inguinal lymph nodes (cN3) require multimodal treatment by chemotherapy and surgery. Even if present in only one node, capsular penetration and extranodal extension in lymph node metastasis carries a high-risk of progression and is classified as pN3, which also requires multimodal treatment.

6.2.1 Management of patients with clinically normal inguinal lymph nodes (cN0)

Risk stratification for the management of patients with clinically normal lymph nodes depends on stage, grade and the presence or absence of lymphovascular invasion in the primary tumour [82]. Tumours with low-risk of metastatic disease are those with superficial penile cancer (pTa, pTis) and low grade. pT1 tumours are a heterogeneous risk group: low risk if they are well differentiated (pT1G1), intermediate-risk group (pT1G2) [83] or high risk (pT1G3 and all higher stages).

Early inguinal lymphadenectomy in clinically node-negative patients is far superior for long-term patient survival compared to therapeutic lymphadenectomy when regional nodal recurrence occurs [84, 85]. One prospective study comparing bilateral lymphadenectomy, radiotherapy and surveillance in clinically node-negative patients reported that 5-year overall survival was significantly better with inguinal lymphadenectomy versus immediate inguinal radiotherapy or that observed with a surveillance strategy (74% vs. 66% and 63%, respectively) [86].

6.2.1.1 Surveillance

The surveillance of regional lymph nodes carries the risk of regional recurrence arising later from existing micrometastatic disease. Patient survival is over 90% with early lymphadenectomy and below 40% with lymphadenectomy for later regional recurrence [87, 88]. This risk must be taken into account when considering surveillance and the patient informed. Surveillance can only be recommended in patients with pTis and pTa penile cancer and with the appropriate caveats in pT1G1 tumours [87-89]. A prerequisite for surveillance is good patient information and compliance.

6.2.1.2 Invasive nodal staging

Staging of the inguinal lymph nodes in cN0 penile cancer requires an invasive procedure since all imaging techniques (US, CT, MRI) are unreliable in excluding small and micrometastatic lymph node involvement. Although CT criteria other than size have been defined for retrospective detection of lymph node metastases, these have not been validated prospectively [90]. Nomograms are unreliable in predicting node involvement [87, 91, 92] (LE: 2b). Fine-needle aspiration cytology does not reliably exclude micrometastatic disease and is not recommended. Instead, pathological risk factors are used to stratify node-negative patients [85, 93] (LE: 2b).

There are two invasive diagnostic procedures, whose efficacy is evidence-based: modified inguinal lymphadenectomy (mILND) and dynamic sentinel-node biopsy (DSNB). Both are standard approaches for invasive diagnosis of inguinal lymph nodes in clinically node-negative patients.

mILND is the standard surgical approach. Both the superficial inguinal lymph nodes from at least the central and both superior Daseler's zones are removed bilaterally [78, 94] (LE: 3), leaving behind the greater saphenous vein.

Dynamic sentinel node biopsy (DSNB) is based on the assumption that primary lymphatic drainage from a penile cancer initially goes to one or only a few inguinal sentinel nodes on each side before further dissemination to more inguinal nodes. Technetium-99m (Tc99m) nanocolloid is injected around the penile cancer site on the day before surgery; patent blue can be injected as well before surgery. A gamma-ray detection probe is used intra-operatively to detect the sentinel node in 97% of cases. The protocol has been standardised for routine use and has a short learning curve [95] (GR: B). DSNB has a reported high sensitivity (90-94%) [95, 96] (LE: 2b). In a pooled meta-analysis of 18 studies, pooled sensitivity was 88%, which improved to 90% with the addition of patent blue [97].

Both methods of invasive regional lymph node staging in cN0 patients may miss micrometastatic disease leading to regional recurrence and greatly reduced long-term survival [84]. The false-negative rate may be as high as 12-15% for DSNB, even in experienced centres [88, 89]. The false-negative rate of mILND is unknown. The patient must be informed of the risk of a false-negative result and the method being used. If lymph node metastasis is found with either method, an ipsilateral radical inguinal lymphadenectomy is indicated.

6.2.2 **Management of patients with palpable inguinal nodes (cN1/cN2)**

With uni- or bilateral palpable inguinal lymph nodes (cN1/cN2), metastatic lymph node disease is very likely and the traditional clinical advice to prescribe antibiotic treatment to exclude lymph node enlargement due to infection is no longer correct. Instead, appropriate oncological diagnosis and treatment should be undertaken without delay before further metastatic spread occurs. In clinically doubtful cases, US-guided fine needle aspiration cytology can be an option [119].

With palpably enlarged inguinal lymph nodes, additional staging using imaging is not useful, except in very obese patients. However, CT or MRI can provide information about the pelvic nodal status. ¹⁸F-FDG-PET/CT can identify additional metastases in lymph-node positive patients [120]. DSNB is not reliable in patients with palpably enlarged and suspicious inguinal lymph nodes and should not be used [121] (LE: 3).

6.2.2.1 **Radical inguinal lymphadenectomy**

In clinically lymph-node positive patients, surgical staging by inguinal lymphadenectomy is indicated. Intra-operative frozen sections may be used to confirm lymph node metastasis, for which an ipsilateral radical inguinal lymphadenectomy is necessary [78, 83].

Radical inguinal lymphadenectomy carries a significant morbidity due to impaired lymph drainage from the legs and often problematic wound healing. Morbidity can be as high as 50% [122] in the presence of significant risk factors such as increased body mass index. However, recent series have reported lower morbidities of about 25% [123, 124] (LE: 2b). Therapeutic radical inguinal lymphadenectomy can be life-saving and should not be underused for fear of associated morbidity [125]. Lymph-node density is a prognostic factor [126].

Tissue handling must be meticulous and take into account the absence of smooth muscle in lymphatic vessel walls. Lymphatic vessels therefore cannot be electrocoagulated and must be closed by ligation or possibly liberal use of clips [127, 128]. Post-operative morbidity is reduced by additional measures to improve drainage, such as stockings, bandaging, inguinal pressure dressings or vacuum suction [129] and prophylactic antibiotics. Advanced cases may require reconstructive surgery for primary wound closure.

The most commonly reported complications in recent series were wound infections (1.2-1.4%), skin necrosis (0.6-4.7%), lymphoedema (5-13.9%) and lymphocele formation (2.1-4%) [123, 124].

Laparoscopic and robot-assisted inguinal lymphadenectomy is feasible, but may not provide any advantage [130-133].

6.2.2.2 **Pelvic lymphadenectomy**

Patients with positive pelvic nodes have a worse prognosis compared to patients with only inguinal nodal metastasis (5-year CSS 71.0% vs. 33.2%) [134]. In the same study with 142 node-positive patients, significant risk factors for pelvic nodal metastasis were the number of positive inguinal nodes (cut-off 3), the diameter of inguinal metastatic nodes (cut-off 30 mm) and extranodal extension. The percentage of pelvic nodal metastases was 0% without any of these risk factors and 57.1% with all three risk factors [134].

If two or more positive lymph nodes, or one node with extracapsular extension (pN3), are found unilaterally, an ipsilateral pelvic lymphadenectomy is indicated. There is no direct lymphatic drainage from penile tumours to the pelvic lymph nodes [135] and lymphadenectomy is therefore not indicated if there is no involvement of inguinal nodes on that side. This recommendation is based on a study in which the rate of positive pelvic nodes was found to be 23% in cases with more than two positive inguinal nodes and 56% in those with more than three positive inguinal nodes, or if there was extracapsular involvement in at least one inguinal node [83, 136] (LE: 2b).

Pelvic lymphadenectomy may be performed simultaneously or as a secondary procedure following definitive histology. If bilateral pelvic dissection is indicated, it can be performed through a midline suprapubic extraperitoneal incision. It is important to avoid unnecessary delay if these procedures are indicated [137].

6.2.2.3 **Adjuvant treatment**

In patients with pN2/pN3 disease, adjuvant chemotherapy is recommended [138] (GR: C) (see Section 6.3.1). This is because a retrospective study reported long-term disease-free survival of 84% in node-positive patients with adjuvant chemotherapy after radical lymph node surgery versus 39% in historical controls without chemotherapy after lymphadenectomy [138].

Although adjuvant radiotherapy has been used after inguinal lymphadenectomy, the data is very limited and it is not generally recommended (see Section 6.2.5). There are no data for neoadjuvant inguinal radiotherapy.

6.2.3 **Management of patients with fixed inguinal nodes (cN3)**

Metastatic disease is always present in these cases. Staging by thoracic, abdominal and pelvic CT scan is necessary to assess the presence of further pelvic nodal disease and systemic metastatic disease. In clinically

unequivocal cases, histological verification by biopsy is not required. Rare cases with reasonable doubt require an excisional or core needle biopsy.

These patients have a poor prognosis and are unlikely to be cured by surgery alone. Upfront surgery is not generally recommended (GR: B) as it is non-curative and usually destructive. Multimodal treatment with neoadjuvant chemotherapy followed by radical lymphadenectomy in clinically responsive cases is recommended [139-141]. Responders to neoadjuvant chemotherapy with post-chemotherapy surgery have been reported to achieve long-term survival in 37% of cases [139]. There may be individual patients with reasons for upfront surgery followed by adjuvant treatment.

6.2.4 **Management of lymph node recurrence**

Patients with regional recurrence after surveillance should be treated similarly to patients with primary cN1/cN2 disease (see Section 6.2.2). Patients with regional recurrence following negative invasive staging by DSNB or modified inguinal lymphadenectomy already have disordered inguinal lymphatic drainage and are at a high-risk of irregular metastatic progression. Patients with inguinal nodal recurrence after therapeutic radical inguinal lymphadenectomy have a 5-year cancer-specific survival of 16% [142].

There is no evidence for the best management in such cases. Multimodal treatment with neoadjuvant and/or adjuvant chemotherapy after radical lymph node surgery is advised.

6.2.5 **The role of radiotherapy for the treatment of lymph node disease**

The use of radiotherapy for nodal disease follows tradition and single-institution policies and is not evidence-based. Despite the lack of data, radiotherapy is widely used in some European countries to manage regional lymph node metastasis in penile cancer.

It has not been reported that neoadjuvant or adjuvant radiotherapy improves oncological outcome in node-positive penile cancer [143]. One prospective trial found that inguinal node dissection was superior to inguinal radiotherapy [144]. Another study reported poor long-term survival in patients with adjuvant inguinal and pelvic radiotherapy [145]. Adjuvant chemotherapy has been reported to be far superior to adjuvant radiotherapy after radical inguinal lymphadenectomy in node-positive patients in one retrospective series [138]. Using the National Cancer Institute Surveillance, Epidemiology and End Results (SEER) Program database, treatment results of 2,458 penile cancer patients treated with either surgery alone or surgery plus EBRT showed that the addition of adjuvant radiotherapy 'had neither a harmful nor a beneficial effect on CSS' [146].

Due to the lack of evidence, radiotherapy in the treatment of lymph node disease in penile cancer is not generally recommended. Prophylactic radiotherapy for cN0 disease is not indicated. Adjuvant inguinal radiotherapy may be considered as an option in selected patients with extracapsular nodal extension (cN3) or as a palliative treatment for surgically irresectable disease.

6.2.6 **Guidelines for treatment strategies for nodal metastases**

Regional lymph nodes	Management of regional lymph nodes is fundamental in the treatment of penile cancer	LE	GR
No palpable inguinal nodes (cN0)	Tis, Ta G1, T1G1: surveillance.	2a	B
	> T1G2: invasive lymph node staging by bilateral modified inguinal lymphadenectomy or DSNB.	2a	B
Palpable inguinal nodes (cN1/cN2)	Radical inguinal lymphadenectomy.		
Fixed inguinal lymph nodes (cN3)	Neoadjuvant chemotherapy followed by radical inguinal lymphadenectomy in responders.		
Pelvic lymphadenectomy	Ipsilateral pelvic lymphadenectomy is indicated if two or more inguinal nodes are involved on one side (pN2) and in extracapsular nodal metastasis (pN3).	2a	B
Adjuvant chemotherapy	Indicated in pN2/pN3 patients after radical lymphadenectomy.	2b	B
Radiotherapy	Radiotherapy is not indicated for the treatment of nodal disease in penile cancer.		

DSNB = dynamic sentinel node biopsy.

6.3 **Chemotherapy**

6.3.1 **Adjuvant chemotherapy in node-positive patients after radical inguinal lymphadenectomy**

Multimodal treatment can improve patient outcome in many tumour entities. Adjuvant chemotherapy after resection of nodal metastases in penile carcinoma has been reported in a few small and heterogeneous series [139, 147-150]. Comparing different small-scale clinical studies is fraught with difficulties.

The value of adjuvant chemotherapy after radical inguinal lymphadenectomy in node-positive penile cancer was demonstrated by an Italian group who reported long-term disease-free survival (DFS) of 84% in 25 consecutive patients treated with 12 adjuvant weekly courses of vincristine, bleomycin, and methotrexate (VBM) during the period 1979-1990 and compared this to a historical control group of 38 consecutive node-positive patients with radical lymphadenectomy (with- or without adjuvant inguinal radiotherapy) who had achieved a DFS rate of only 39% [139].

This group has also published results of a chemotherapy regimen adjuvant to radical lymphadenectomy in stage pN2-3 patients receiving three courses of cisplatin and 5-FU which they had been using since 1991 with lower toxicity and even better results compared to VBM [149] (LE: 2b). The same group has been using an adjuvant taxane-based regimen since 2004 (cisplatin, 5-FU plus paclitaxel or docetaxel [TPF]) in 19 node-positive patients receiving 3-4 cycles of TPF after resection of pN2-3 disease [150]. Of those patients, 52.6% were disease-free after a median follow up of 42 months and tolerability was good. Results of adjuvant treatment with paclitaxel and cisplatin also improved outcome [151].

The use of adjuvant chemotherapy is recommended, in particular when the administration of the triple combination chemotherapy is feasible, and curative treatment is aimed for (LE: 2b).

No data for the adjuvant chemotherapeutic treatment of penile carcinoma in stage pN1 are available. The administration of an adjuvant treatment in pN1 disease is therefore recommended only in clinical trials.

6.3.2 Neoadjuvant chemotherapy in patients with fixed or relapsed inguinal nodes

Bulky inguinal lymph node enlargement (cN3) indicates extensive lymphatic metastatic disease. Primary lymph node surgery is not generally recommended (GR: B). Complete surgical resection is unlikely and only a few patients will benefit from surgery alone.

Very limited data is available on neoadjuvant chemotherapy before inguinal lymph node surgery. This approach enables early treatment of likely systemic disease and downstaging of inguinal lymph node disease. Complete surgical treatment is possible with a good clinical response.

Results were modest in retrospective studies of 5-20 patients treated with bleomycin-vincristine-methotrexate (BVM) and bleomycin-methotrexate-cisplatin (BMP) treatments [140, 141, 152] and in the confirmatory BMP trial of the Southwest Oncology Group [153]. However, treatment-related toxicity was unacceptable due to bleomycin-related mortality.

Cisplatin/5-FU (PF) chemotherapy achieved a response rate of 25-50% and more acceptable tolerability [154, 155]. Over a period of 30 years, five different neoadjuvant chemotherapy regimens were used in 20 patients [78], with long-term survival in 37% of chemotherapy responders who underwent surgery. In EORTC study 30992, 26 patients with locally advanced or metastatic disease received irinotecan and cisplatin chemotherapy. Although the study did not meet its primary endpoint (response rate), there were three cases of pathologically complete remissions (pCR) [156].

A phase II trial evaluated treatment with four cycles of neoadjuvant paclitaxel, cisplatin, and ifosfamide (TIP). An objective response was reported in half of 30 patients, including three pCRs, which was a marginally significant predictor of survival. The estimated median time to progression (TTP) was 8.1 months and the median overall survival was 17.1 months [157] (LE: 2a).

Similarities between penile SCC and head and neck SCC led to the evaluation in penile cancer of chemotherapy regimens with an efficacy in head and neck SCC, including taxanes. The combination of cisplatin and 5-FU plus a taxane has been used in an neoadjuvant and adjuvant setting [150]. An overall objective response rate of 44% was reported in 28 patients treated neoadjuvantly, including 14% pCR (LE: 2b).

Similarly, a Cancer Research UK phase 2 trial with TPF (using only docetaxel) reported an objective response of 38.5% in 29 locally advanced or metastatic patients, although not meeting the primary endpoint. However, there was significant toxicity [158] (LE: 2a).

Overall, these results support the use of neoadjuvant chemotherapy for patients with fixed, unresectable nodal disease, particularly with a triple combination, including cisplatin and a taxane, whenever feasible (LE: 2a; GR: B).

There are hardly any data concerning radiochemotherapy with lymph-node surgery in penile cancer (very old, very few patients). Radiochemotherapy is only for clinical trials [159].

6.3.3 Palliative chemotherapy in advanced and relapsed disease

A recent retrospective study of individual patient data of 140 men with advanced penile SCC reported that visceral metastases and an ECOG-performance status > 1 were independent prognostic factors, and that cisplatin-based regimens had better outcomes than non-cisplatin-based regimens after adjusting for prognostic factors [160] (LE: 3).

In clinical practice, however, first-line chemotherapy regimens are variable. Before taxanes were introduced, the data were limited by small numbers, patient heterogeneity and its retrospective nature (except

for the EORTC trial [156]). Initial response rates ranged from 25% to 100%, but very few sustained responses and very few long-term survivors. The introduction of taxanes into penile cancer chemotherapy has enhanced the activity and efficacy of the regimens used [78, 140, 141, 151-158, 161].

There is virtually no data on second-line chemotherapy in penile cancer. One report using second-line paclitaxel monotherapy reported an initial response rate under 30% which therefore may be a reasonable option. However, no patient survived [162] (LE: 2a; GR: B). Anecdotally, a benefit has been observed by combining cisplatin with gemcitabine [163] (LE: 4).

6.3.4 ***Intra-arterial chemotherapy***

Intra-arterial chemotherapy has been trialled in locally advanced cases, especially cisplatin and gemcitabine in small case series [164-167]. Apart from a limited clinical response, outcome was not significantly improved.

6.3.5 ***Targeted therapy***

Targeted drugs have been used as second-line treatment and they could be considered as single-agent treatment in refractory cases. Anti-epidermal growth factor receptor (EGFR) targeted monotherapy has been trialled because EGFR is expressed in penile SCC [164, 165] and assumed similarities with head and neck SCC [165, 166]. There have been other studies, particularly with the anti-EGFR monoclonal antibodies, panitumumab and cetuximab. Some activity of tyrosine kinase inhibitors has been reported as well [167]. Further clinical investigations are needed (LE: 4).

6.3.6 ***Guidelines for chemotherapy in penile cancer patients***

Recommendations	LE	GR
Adjuvant chemotherapy (3-4 cycles of TPF) is an option for patients with pN2-3 tumours [150].	2b	C
Neoadjuvant chemotherapy (four cycles of a cisplatin and taxane-based regimen) followed by radical surgery is recommended in patients with non-resectable or recurrent lymph node metastases [150, 156].	2a	B
Chemotherapy for systemic disease is an option in patients with limited metastatic load.	3	C

TPF = cisplatin.

7. FOLLOW-UP

7.1 ***Rationale for follow-up***

The early detection of recurrence during follow-up increases the likelihood of curative treatment. Local recurrence does not significantly reduce long-term survival if successfully treated. In contrast, disease that has spread to the inguinal lymph nodes greatly reduces the rate of long-term disease-specific survival. Follow-up is also important in the detection and management of treatment-related complications.

Local or regional nodal recurrences usually occur within 2 years of primary treatment [78]. After 5 years, all recurrences were either local recurrences or new primary lesions [78]. These results support an intensive follow-up regimen during the first 2 years, with a less intensive follow-up after this for a total of at least 5 years. Follow-up after 5 years may be omitted in motivated patients reliably able to continue to carry out regular self-examination [78].

7.1.1 ***When and how to follow-up***

In patients with negative inguinal nodes after local treatment, follow-up should include physical examination of the penis and the groins for local and/or regional recurrence. Additional imaging has no proven benefit.

Follow-up also depends on the primary treatment modality. Histology from the glans should be obtained to confirm disease-free status following laser ablation or topical chemotherapy.

After potentially curative treatment for inguinal nodal metastases, CT or MRI imaging for the detection of systemic disease should be performed at 3-monthly intervals for the first 2 years so patients can benefit from adjuvant chemotherapy.

Although rarely late local recurrences may still occur, life-threatening metastases become very unusual after 5 years. This means regular follow-up can be stopped after 5 years, provided the patient understands the need to report any local changes immediately [168]. In patients unlikely to self-examine, long-term follow-up may be necessary.

7.1.2 Recurrence of the primary tumour

Local recurrence is more likely with all types of local organ-preserving treatment, i.e. after local excision, laser treatment, brachytherapy and associated therapies. However, it is very unlikely to increase the risk of dying from the disease in contrast to regional recurrence [78, 169]. Local recurrence occurred during the first 2 years in up to 27% of patients treated with penis-preserving modalities [170]. After partial penectomy, the risk of local recurrence is about 4-5% [78, 169, 170].

Local recurrence is easily detected by physical examination by the patient himself or the physician. Patient education is an essential part of follow-up and the patient is urged to visit a specialist if any changes are seen.

7.1.3 Regional recurrence

Most regional recurrences occur within during the first 2 years of diagnosis and treatment, irrespective of whether a surveillance strategy has been used or a sentinel-node based management or modified inguinal lymphadenectomy.

Although very unlikely, regional recurrence can occur unexpectedly after 2 years. It is therefore wise to continue close follow-up in these patients, for whom self-examination is very important [171]. The highest rate of regional recurrence (9%) occurs in patients managed using a surveillance strategy, while the lowest is in patients who have undergone invasive nodal staging by modified inguinal lymphadenectomy or DSNB and whose lymph nodes were negative (2.3%).

The use of US and fine needle aspiration cytology (FNAC) in suspicious cases has improved the early detection rate of regional recurrence [66, 171, 172]. There are no data to support the routine use of CT or MRI for the follow-up of regional nodes.

Patients who have had surgical treatment for lymph node metastases without adjuvant treatment have an increased risk of regional recurrence of 19% [78]. Regional recurrence requires timely treatment by radical inguinal lymphadenectomy and adjuvant therapy (see Section 6).

7.1.4 Guidelines for follow-up in penile cancer

	Interval of follow-up		Examinations and investigations	Minimum duration of follow-up	GR
	Years 1-2	Years 3-5			
Recommendations for follow-up of the primary tumour					
Penile-preserving treatment	3 months	6 months	Regular physician or self-examination. Repeat biopsy after topical or laser treatment for CIS.	5 years	C
Amputation	3 months	1 year	Regular physician or self-examination.	5 years	C
Recommendations for follow-up of the inguinal lymph nodes					
Surveillance	3 months	6 months	Regular physician or self-examination.	5 years	C
pN0 at initial treatment	3 months	1 year	Regular physician or self-examination. Ultrasound with FNAB optional.	5 years	C
pN+ at initial treatment	3 months	6 months	Regular physician or self-examination. Ultrasound with FNAC optional, CT/MRI optional.	5 years	C

CIS = carcinoma in situ; CT = computed tomography; FNAB = fine-needle aspiration biopsy; FNAC = fine-needle aspiration cytology; MRI = magnetic resonance imaging.

7.2 Quality of life

7.2.1 Consequences after penile cancer treatment

In patients with long-term survival after penile cancer treatment, sexual dysfunction, voiding problems and cosmetic penile appearance may adversely affect the patient's quality of life (QoL) [173]. There is very little data on sexual function and QoL after treatment for penile cancer.

7.2.2 Sexual activity and quality of life after laser treatment

A retrospective interview-based Swedish study after laser treatment for penile CIS [92] in 58/67 surviving patients with a mean age of 63 years, of whom 46 participated, reported a marked decrease in some sexual practices, such as manual stimulation, caressing and fellatio, but a general satisfaction with life overall and in other domains of life, including their sex life, similar to that of the general Swedish population.

A large study on CO₂ laser treatment of penile cancer in 224 patients reported no problems with erectile capability or sexual function following treatment [84]. In another study [95], no sexual dysfunction occurred in 19 patients treated.

7.2.3 Sexual activity after glans resurfacing

In one study with 10 patients [98], 7/10 completed questionnaires (International Index of Erectile Function [IIEF-5] and a non-validated 9-item questionnaire) at their 6-month follow-up visit. There was no erectile dysfunction according to the median IIEF-5 score of 24. All patients who were sexually active before treatment were active again within 3-5 months. According to the (non-validated) questionnaire, 7/7 patients stated that the sensation at the tip of their penis was either no different or better after surgery and that they had erections within 2-3 weeks of surgery. Six out of seven patients had had sexual intercourse within 3 months of surgery and 5/7 patients felt that their sex life had improved. Overall patient satisfaction with glans resurfacing was high.

7.2.4 Sexual activity after glansectomy

Two studies reported sexual function after glansectomy [100, 101]. In one study (n = 68) with unclear methodology [100], 79% did not report any decline in spontaneous erection, rigidity and penetrative capacity after surgery, while 75% reported recovery of orgasm. In another study [101], all 12 patients had returned to 'normal' sexual activity at 1 month after surgery.

7.2.5 Sexual function after partial penectomy

Sexual function after partial penectomy was reported by three studies [174-176]. The IIEF questionnaire was used in 18 patients with a mean age of 52 years [174]. Post-operative scores were statistically worse for all domains of sexual function after partial penectomy. After surgery, 55.6% of patients had erectile function that allowed sexual intercourse. In patients who did not resume sexual intercourse after partial penectomy, 50% were ashamed of their small penis and missing glans, while another third blamed surgical complications. Of those who had resumed sexual intercourse, 66.7% reported the same frequency and level of sexual activity as before surgery, while 72.2% continued to have ejaculation and orgasm every time they had sexual activity. Overall, only 33.3% maintained their pre-operative frequency of sexual intercourse and were satisfied with their overall sex life.

An 'Overall Sexual Functioning Questionnaire' was used in 14/18 patients with a median time since surgery of 11.5 months (range 6-72) [175]. Prior to surgery, all patients had normal erectile function and at least one intercourse per month. In 9/14 patients, overall sexual functioning was 'normal' or 'slightly decreased', while 3/14 patients had no sexual intercourse after surgery. Alei et al. showed an improvement in erectile function with time [176].

7.2.6 Quality of life after partial penectomy

Several qualitative and quantitative instruments were used to assess 'psychological behaviour and adjustment' and 'social activity' as QoL indicators [175]. Patients reported fears of mutilation and of loss of sexual pleasure, as well as fear of dying and what this would mean for their families. Patients said family and partners were important in overcoming difficulties following surgery. The study reported no significant levels of anxiety and depression on the GHQ-12 (General Health Questionnaire) and HAD scale (Hospital Anxiety and Depression Scale), 'Social activity' remained the same after surgery in terms of living conditions, family life and social interactions.

7.3 Total phallic reconstruction

There is very limited data about total phallic reconstruction [117, 177, 178] following full- or near-total penile amputation. It is not possible to restore function. Cosmetically acceptable results are obtainable.

7.4 Specialised care

It is possible to cure almost 80% of penile cancer patients at all stages. Whenever possible, organ-preserving treatment should be offered [47] because it permits better QoL and sexual function than with partial penectomy. Patients should be referred to experienced centre. Psychological support is very important for penile cancer patients.

1. INTRODUCTION

1.1 Aim

Lower urinary tract symptoms (LUTS) are a common complaint in adult men with a major impact on quality of life (QoL), and substantial personal and societal expenditures. The present Guidelines offer practical evidence-based guidance on the assessment and treatment of men aged 40 years or older with various non-neurogenic benign forms of LUTS. The understanding of the LUT as a functional unit, and the multifactorial aetiology of associated symptoms, means that LUTS now constitute the main focus, rather than the former emphasis on Benign Prostatic Hyperplasia (BPH).

1.2 Publication history

Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates. A shorter reference document, the Pocket Guidelines, is also available, both in print and as a mobile application, presenting the main findings of the Non-neurogenic Male LUTS Guidelines. These versions are abridged and therefore may require consultation with the full text version. All are available through the EAU website: <http://www.uroweb.org/guidelines/>.

For the 2015 Guidelines, the text has been significantly reduced so that only key information is included and re-formatted according to the EAU non-oncology template so that all Guidelines follow a similar format. This document was peer-reviewed prior to publication.

1.3 Panel composition

The Non-neurogenic Male LUTS Guidelines Panel consists of experts with a urological and epidemiological background. Although the Guidelines are written primarily for urologists, they can also be used by general practitioners, patients or other stakeholders.

2. METHODS

A systematic literature search was carried out by the Panel for articles in English language published in the PubMed, Medline, Web of Science, and Cochrane databases between 1966 and 31st December 2013 [1-4]. The search terms included 'lower urinary tract symptoms', 'benign prostatic hyperplasia', 'detrusor overactivity', 'overactive bladder', 'nocturia', and 'nocturnal polyuria', in combination with the pre-specified diagnostic tests, the various treatment modalities and the search limits, 'humans', 'adult men', 'review', 'randomised clinical trials', 'clinical trials', and 'meta-analysis'. References used in this text are graded according to their Level of Evidence (LE) and Guidelines are given a Grade of Recommendation (GR). In this 2015 EAU Guidelines compilation, all standard information on LE and GR has been taken out of the individual Guidelines topics for the sake of brevity. The methodology section (see the introduction chapter of the complete book) and supplementary online material Tables S.1 and S.2 outlines the LE and GR criteria which are used throughout the Guidelines, according to a classification system modified from the Oxford Centre for Evidence-based Medicine Levels of Evidence (modified March 2009) [1].

For Chapter 3B (Diagnostic evaluation), the Panel used the Delphi technique consensus approach. The Delphi method infers that decisions captured systematically from a structured group of individuals (the Panel) are more valid than those from unstructured groups. When published information is scarce, experts can make inferences using other data from comparable contexts. Using bespoke software (www.acord.it), propositions were put to experts who voted their preference. The results for the group were then sent back so participants could review their responses in the context of group-wide results. This was done anonymously, so review was free of peer group pressure. The web-based system offered the option to comment and justify decisions anonymously, and a second round of anonymous voting took place. Three iterations of the process were used, so that opinions of the Panel members converged towards the consensus 'correct' answer. The Panel pre-determined the threshold for consensus at 77% (7 out of 9) in regards to agreeing recommendations. The Panel classified diagnostic tests into three categories: 'must', 'should', and 'may'. 'Must' presents the highest level of obligation. 'Should' presents an intermediate level, and 'may' expresses the lowest level of obligation.

Subsections for the various types of conservative treatments, drugs, and operations are presented in a homogeneous structure listing 'mechanism of action', 'efficacy' with a table of high LE trials, 'safety' and 'practical considerations'. 'Grades of Recommendation' (GR) are derived from the relevant articles according to the modified classification system from the Oxford Centre for Evidence-based Medicine [1] (see supplementary online material Table S.2).

Where possible, recommendations are based on the strongest clinically relevant data. When recommendations are graded, there is no automatic relationship between the LE and GR. The availability of randomised controlled trials (RCTs) may not necessarily translate into a Grade A recommendation if there are methodological limitations or a disparity in published results, uncertainty about the balance of desirable and undesirable effects, uncertainty or variability in patients' values and preferences, or uncertainty about whether the intervention represents a wise use of resources. Alternatively, lack of high-level evidence does not preclude a Grade A recommendation where there is considerable clinical experience and consensus, or situations where corroborating studies cannot be performed, perhaps for ethical, financial or other reasons. Such a situation is indicated in the text with an asterisk to denote 'upgraded based on Panel consensus'. The quality of the scientific evidence is a major factor, but it has to be balanced against benefits, burdens, personal values and preferences when a Grade of Recommendation is assigned.

The Working Panel intends to update the content and recommendations regularly, according to the given structure and classification systems.

2.1 Patients to whom the guidelines apply

Recommendations apply to men aged 40 years or older who seek professional help for LUTS in various non-neurogenic and non-malignant conditions, such as LUTS/Benign Prostatic Obstruction (BPO), detrusor overactivity/overactive bladder (OAB), or nocturnal polyuria. Men with other contexts of LUT disease (e.g. concomitant neurological diseases, young age, prior LUT disease or surgery) usually require a more extensive work-up, which is not covered in these Guidelines, but may include several tests mentioned in the following section. EAU Guidelines on Neuro-Urology, Urinary Incontinence, Urological Infections, Urolithiasis, or malignant diseases of the LUT have been developed by other EAU Guidelines Panels (www.uroweb.org).

3. THE GUIDELINE

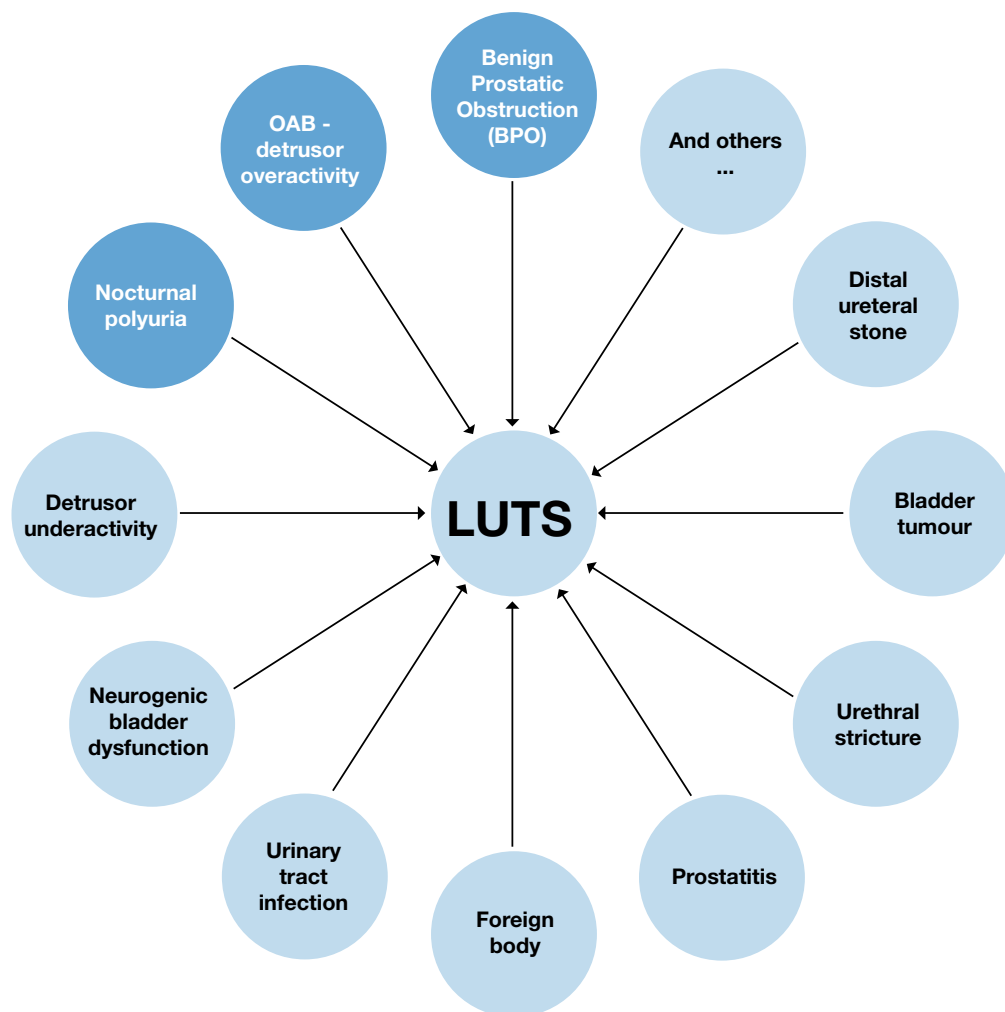

3A EPIDEMIOLOGY, AETIOLOGY AND PATHOPHYSIOLOGY

LUTS can be divided into storage, voiding and post-micturition symptoms [2]. LUTS are prevalent, cause bother and impair QoL [5-8]. They are strongly associated with ageing [5, 6], so associated costs and burden are likely to continue to increase overall in the future [6, 9].

Most elderly men report having at least one LUTS [6]. However, clinically meaningful prevalences are lower as symptoms may be mild or not very bothersome [8]. LUTS progress dynamically: for some individuals LUTS persist and progress over long time periods, and for others they remit [6].

LUTS have traditionally been related to bladder outlet obstruction (BOO), which is often caused by benign prostatic enlargement (BPE) resulting from the histologic condition of benign prostatic hyperplasia (BPH) [2, 7]. Recent studies have shown, however, that LUTS are often unrelated to prostate [3, 6]. Bladder dysfunction may also cause LUTS, including detrusor overactivity/OAB, detrusor underactivity/underactive bladder, as well as other structural or functional abnormalities of the urinary tract [3]. In addition, many non-urological conditions also contribute to LUTS, especially nocturia [6]. Figure 1 illustrates the potential causes of LUTS. In any single person complaining of LUTS, it is common for more than one of these factors to be present.

Figure 1: Causes of male lower urinary tract symptoms (LUTS)

3B DIAGNOSTIC EVALUATION

Tests are useful for diagnosis, monitoring, assessing the prognosis of disease progression, treatment planning, and the prediction of treatment outcome. The clinical assessment of patients with LUTS has two main objectives:

- To consider the differential diagnoses, since the origin of male LUTS are multifactorial. The relevant EAU Guidelines on the management of applicable conditions should be followed in these cases.
- To define the clinical profile of men with LUTS in order to provide appropriate care. The assessment should ascertain treatment options and identify men at risk of disease progression.

3B.1 Medical History

The importance of assessing the patient's history is well-recognised [4, 10, 11].

A medical history aims to identify the potential causes and relevant comorbidities, including medical and neurological diseases. In addition, it is recommended that current medication, lifestyle habits, emotional and psychological factors are reviewed. The Panel recognises the need to discuss LUTS and the therapeutic pathway from the patient's perspective. This includes reassuring the patient that there is no definite relation between LUTS and prostate cancer (PCa) [12, 13].

As part of the urological/surgical history, a self-completed validated symptom questionnaire (see section 3B.2) should be assessed to objectify and quantify LUTS. Voiding diaries are particularly beneficial when assessing patients with nocturia and/or other storage LUTS (see section 3B.3 'frequency volume chart'). When relevant, sexual function should be investigated, preferably with validated symptom questionnaires such as the International Index for Erectile Function (IIEF).

Recommendation	LE	GR
A medical history must always be taken from men with LUTS.	4	A*

**Upgraded based on Panel consensus. LUTS = lower urinary tract symptoms.*

3B.2 Symptom score questionnaires

All published guidelines for male LUTS/BPH recommend using validated symptom score questionnaires [4, 10, 11]. Several questionnaires have been developed which are sensitive to symptom changes and can be used to monitor treatment [14-20]. Symptom scores are helpful in quantifying the patient's LUTS and in identifying which type of symptoms are predominant, yet they are not disease-, age- or gender-specific.

3B.2.1 The International Prostate Symptom Score (IPSS)

The IPSS is an 8-item questionnaire, consisting of seven symptom questions and one QoL question [15]. The IPSS score is categorised as 'asymptomatic' (0 points), 'mildly symptomatic' (1-7 points), 'moderately symptomatic' (8-19 points), and 'severely symptomatic' (20-35 points). Limitations include lack of assessment of incontinence, post-micturition symptoms, and bother caused by each separate symptom.

3B.2.2 The International Consultation on Incontinence Questionnaire (ICIQ-MLUTS)

The ICIQ-MLUTS was created from the ICS Male questionnaire. It is a widely used and validated patient-completed questionnaire [16]. It contains 13 items, with subscales for nocturia and OAB, and is available in 17 languages.

3B.2.3 Danish Prostate Symptom Score (DAN-PSS)

The DAN-PSS [18] is a symptom score used mainly in Denmark and Finland. The IPSS includes only one overall QoL question. The ICIQ-MLUTS and DAN-PSS measure the bother of each individual LUTS.

Recommendation	LE	GR
A validated symptom score questionnaire with QoL question(s) should be used for the routine assessment of male LUTS in all patients and should be applied for re-evaluation of LUTS during treatment.	3	B

LUTS = lower urinary tract symptoms; QoL = quality of life.

3B.3 Frequency volume charts and bladder diaries

The recording of volume and time of each void by the patient is referred to as a frequency volume chart (FVC). Inclusion of additional information such as fluid intake, use of pads, activities during recording, or symptom scores is termed a bladder diary [2]. Parameters that can be derived from the FVC bladder diary include: day-time and night-time voiding frequency, total voided volume, the fraction of urine production during the night (nocturnal polyuria index [NPI]), and volume of individual voids.

The mean 24-hour urine production is subject to considerable variation. Likewise, circumstantial influence and intra-individual variation cause FVC parameters to fluctuate, though there is comparatively little data [21, 22]. The FVC diary is particularly relevant in nocturia, where it underpins the categorisation of underlying mechanism(s) [23-25]. The use of FVCs may cause a 'bladder training effect', and influence the frequency of nocturnal voids [26].

The duration of observation during FVC needs to be long enough to avoid sampling errors, but short enough to avoid non-compliance [27]. A systematic review of the available literature recommended FVC should continue for 3 or more days [28].

Recommendations	LE	GR
Micturition frequency volume charts or bladder diaries should be used to assess male LUTS with a prominent storage component or nocturia.	3	B
Frequency volume charts should be performed for the duration of at least 3 days.	2b	B

LUTS = lower urinary tract symptoms.

3B.4 Physical examination and digital-rectal examination

Physical examination to seek potential influences on LUTS, particularly focussing on the suprapubic area, the external genitalia, the perineum and lower limbs. Urethral discharge, meatal stenosis, phimosis and penile cancer must be identified if present.

3B.4.1 Digital-rectal examination and prostate size evaluation

Digital-rectal examination (DRE) is the simplest way to assess prostate volume, but correct estimation is not easy to achieve. Quality-control procedures for DRE have been described [29]. Transrectal ultrasound (TRUS)

is more accurate in determining prostate volume than DRE. Underestimation of prostate volume by DRE increases with increasing TRUS volume, particularly where the volume is > 30 mL [30]. A model of visual aids has been developed to help urologists estimate prostate volume more accurately [31]. One study concluded that DRE was sufficient to discriminate between prostate volumes > or < than 50 mL [32].

Recommendation	LE	GR
Physical examination including DRE should be a routine part of the assessment of male LUTS.	3	B

DRE = digital-rectal examination; LUTS = lower urinary tract symptoms.

3B.5 Urinalysis

Urinalysis (dipstick or sediment) must be included in the primary evaluation of any patient presenting with LUTS to determine conditions, such as UTI, microhaematuria and diabetes mellitus. If abnormal findings are detected further tests are recommended according to other EAU Guidelines, including Guidelines on urinary tract cancers and urological infections [33-36].

Urinalysis is recommended in most Guidelines in the primary management of patients with LUTS [37, 38]. There is limited evidence, yet there is general expert consensus that the benefits outweigh the costs [39]. The value of urinary dipstick/microscopy for diagnosing UTI in LUTS without acute frequency and dysuria has recently been questioned [40].

Recommendation	LE	GR
Urinalysis (by dipstick or urinary sediment) must be used in the assessment of male LUTS.	3	A*

**Upgraded based on Panel consensus. LUTS = lower urinary tract symptoms.*

3B.6 Prostate-specific antigen (PSA)

3B.6.1 PSA and the prediction of prostatic volume

Several reports have demonstrated the reliability of measuring the PSA concentration for predicting prostate volume. The pooled analysis of placebo-controlled BPH trials show that PSA has a good predictive value for assessing prostate volume, with areas under the curve of 0.76 - 0.78 for various prostate volume thresholds (30 mL, 40 mL, and 50 mL). To achieve a specificity of 70%, whilst maintaining a sensitivity between 65-70%, approximate age-specific criteria for detecting men with prostate glands exceeding 40 mL are PSA > 1.6 ng/mL, > 2.0 ng/mL, and > 2.3 ng/mL, for men with BPH in their 50s, 60s, and 70s, respectively [41].

A strong association between PSA and prostate volume was found in a large community-based study in the Netherlands [42]. A PSA threshold value of 1.5 ng/mL could best predict a prostate volume of > 30 mL, with a positive predictive value (PPV) of 78%. The prediction of prostate volume can also be based on total and free PSA. Both PSA forms predict the TRUS prostate volume (\pm 20%) in > 90% of the cases [43, 44].

3B.6.2 PSA and the probability of PCa

The role of PSA in the diagnosis of PCa is presented by the EAU Guidelines on Prostate Cancer [45]. The potential benefits and harms of using serum PSA testing to diagnose PCa in men with LUTS should be discussed.

3B.6.3 PSA and the prediction of BPO-related outcomes

Serum PSA is a stronger predictor of prostate growth than prostate volume [46]. In addition, the PLESS study showed that PSA also predicted the changes in symptoms, QoL/bother, and maximum flow rate (Q_{max}) [47]. In a longitudinal study of men managed conservatively, PSA was a highly significant predictor of clinical progression [48].

In the placebo arms of large double-blind studies, baseline serum PSA predicted the risk of acute urinary retention (AUR) and BPE-related surgery [49, 50]. An equivalent link was also confirmed by the Olmsted County Study. The risk for treatment was higher in men with a baseline PSA of >1.4 ng/mL [51]. Patients with BPO seem to have a higher PSA level and larger prostate volumes. The positive predictive values of PSA for the detection of BPO was recently shown to be 68% [52]. In an epidemiological study, elevated free PSA levels could predict clinical BPH, independent of total PSA levels [53].

Recommendation	LE	GR
PSA measurement should be performed only if a diagnosis of PCa will change the management or if PSA can assist in decision-making in patients at risk of progression of BPE.	1b	A

BPE = benign prostate enlargement; PCa = prostate cancer; PSA = prostate-specific antigen.

3B.7 Renal function measurement

Renal function may be assessed by serum creatinine or estimated glomerular filtration rate (eGFR).

Hydronephrosis, renal insufficiency or urinary retention are more prevalent in patients with signs or symptoms of BPO [54]. Even though BPO may be responsible for these complications, there is no conclusive evidence on the mechanism [55].

One study reported 11% of men with LUTS had renal insufficiency [54]. Neither symptom score nor QoL was associated with the serum creatinine concentration, and diabetes mellitus or hypertension were the most likely causes of the elevated creatinine concentration. Comiter et al. [56] reported that non-neurogenic voiding dysfunction is not a risk factor for elevated creatinine levels. Koch et al. [57] concluded that only those with an elevated creatinine level require investigational ultrasound of the kidney.

In the Olmsted County community-dwelling men, there was a cross-sectional association between signs and symptoms of BPO (though not prostate volume) and chronic kidney disease (CKD) [58]. In 2,741 consecutive patients who presented with LUTS, decreased Q_{max} , a history of hypertension and/or diabetes were associated with CKD [59]. Another study demonstrated a correlation between Q_{max} and eGFR in middle-aged men with moderate-to-severe LUTS [60]. Patients with renal insufficiency are at an increased risk of developing post-operative complications [61].

Recommendation	LE	GR
Renal function assessment must be performed if renal impairment is suspected, based on history and clinical examination or in the presence of hydronephrosis or when considering surgical treatment for male LUTS.	3	A*

**Upgraded based on Panel consensus. LUTS = lower urinary tract symptoms.*

3B.8 Post-void residual urine

Post-void residual (PVR) urine can be assessed by transabdominal US, bladder scan or catheterisation. PVR is not necessarily associated with BOO, since high PVR volumes can be a consequence of obstruction and/or poor detrusor function (detrusor underactivity) [62, 63].

At PVR of 50 mL, the diagnostic accuracy of PVR measurement has a positive predictive value (PPV) of 63% and a negative predictive value (NPV) of 52% to predict BOO [64]. A large PVR measurement is not a contraindication to watchful waiting (WW) or medical therapy, although large PVR may indicate a poor response to treatment and especially to WW. In both the MTOPS and ALTESS studies, a high baseline PVR was associated with an increased risk of symptom deterioration [49, 50].

Monitoring of changes in PVR over time may allow for identification of patients at risk of AUR [50]. This is of particular importance for the treatment of patients using antimuscarinic medication. In contrast, baseline PVR has little prognostic value for the risk of BPE-related invasive therapy in patients on α_1 -blocker or WW [65]. However, due to large test-retest variability and lack of outcome studies, no PVR threshold for treatment decision has yet been established and this is a research priority.

Recommendation	LE	GR
Measurement of post-void residual in male LUTS should be a routine part of the assessment.	3	B

LUTS = lower urinary tract symptoms.

3B.9 Uroflowmetry

Urinary flow rate assessment is a widely used non-invasive urodynamic test that evaluates the functioning of the LUT. Key parameters are Q_{max} and flow pattern. Uroflowmetry parameters should preferably be evaluated with voided volume > 150 mL. Q_{max} is prone to within-subject variation [66, 67]; it is therefore useful to repeat uroflowmetry measurements, especially if the voided volume is < 150 mL, or Q_{max} or flow pattern is abnormal.

The diagnostic accuracy of uroflowmetry for detecting BOO varies considerably, and is substantially influenced by threshold values. A threshold value of Q_{max} of 10 mL/s has a specificity of 70%, a PPV of 70% and a sensitivity of 47% for BOO. The specificity using a threshold Q_{max} of 15 mL/s was 38%, the PPV 67% and the sensitivity 82% [68]. If Q_{max} is ≥ 15 mL/s, physiological compensatory processes mean that BOO cannot be excluded. Low Q_{max} can arise as a consequence of BOO [69], detrusor underactivity or an underfilled bladder [70]. Thus, it is limited as a diagnostic test because it is unable to discriminate between the underlying mechanisms. Specificity can be improved by repeated flow rate testing. Uroflowmetry can be used for monitoring treatment outcomes [71] and correlating symptoms with objective findings.

Recommendation	LE	GR
Uroflowmetry in the initial assessment of male LUTS may be performed and should be performed prior to any treatment.	2b	B

LUTS = lower urinary tract symptoms.

3B.10 Imaging

3B.10.1 Upper urinary tract

Routine imaging of the upper urinary tract in men with LUTS is not recommended, as they are not at increased risk for upper tract malignancy or other abnormalities when compared to the overall population [57, 72-74].

Several arguments support the use of renal US in preference to intravenous urography (IVU).

US allows for a better characterisation of renal masses, the possibility of investigating the liver and retroperitoneum, and simultaneous evaluation of the bladder, PVR and prostate, together with a lower cost, lower radiation dose and less side-effects [72].

Recommendation	LE	GR
Imaging of the upper urinary tract (with US) in men with LUTS should be performed in patients with a large PVR, haematuria or a history of urolithiasis.	3	B

LUTS = lower urinary tract symptoms; PVR = post-void residual; US= ultrasound.

3B.10.2 Prostate

Imaging of the prostate can be performed by transabdominal US, TRUS, computed tomography, and magnetic resonance imaging (MRI). However, in daily practice, prostate imaging is performed by TRUS or transabdominal US [72].

3B.10.2.1 Prostate size and shape

Assessment of prostate size is important for the selection of interventional treatment, i.e. open prostatectomy, enucleation techniques, transurethral resection, TUIP, or minimally invasive therapies. It is also important prior to treatment with 5-ARIs. Prostate volume predicts the development of progressive symptoms and complications [74].

TRUS is superior to suprapubic (transabdominal) volume measurement [75, 76]. The presence of a median lobe may guide treatment choice in patients scheduled for a minimally invasive approach.

Recommendations	LE	GR
When considering medical treatment for male LUTS, imaging of the prostate (either by TRUS or transabdominal US) should be performed if it assists the choice of the appropriate drug.	3	B
When considering surgical treatment, imaging of the prostate (either by TRUS or transabdominal US) should be performed.	3	B

LUTS = lower urinary tract symptoms; TRUS = transrectal ultrasound.

3B.10.3 Prostatic configuration/intravesical prostatic protrusion (IPP)

Prostatic configuration has been evaluated with TRUS, using the concept of the presumed circle area ratio (PCAR) [77]. PCAR evaluates how closely the transverse US image of the prostate approaches a circular shape. The ratio tends toward 1 as the prostate becomes more circular. PCAR sensitivity was 77% for diagnosing BPO when PCAR was > 0.8, with 75% specificity [77].

Ultrasound measurement of intravesical prostatic protrusion (IPP) assesses the distance between the tip of the prostate median lobe and bladder neck in the midsagittal plane, using a suprapubically positioned US scanner, with the bladder volume at 150-250 mL; grade I protrusion is 0-4.9 mm, grade II is 5-10 mm and grade III is >10 mm.

IPP correlates well with BPO (presence and severity) on urodynamic testing, with a PPV of 94% and a NPV of 79% [78]. IPP may correlate with prostate volume, detrusor overactivity, bladder compliance, detrusor pressure at maximum urinary flow, BOO index and PVR, and negatively correlates with Q_{max} [79]. IPP also seems to predict successful outcome of trial without catheter (TWOC) after acute urinary retention [80, 81]. No information with regard to intra- or inter-observer variability and learning curve is yet available. IPP may be a feasible option to infer BPO in men with LUTS. The role of IPP as a non-invasive alternative to pressure flow studies (PFS) in the assessment of male LUTS is under evaluation.

3B.10.4 Bladder/detrusor wall thickness and ultrasound-estimated bladder weight

For bladder wall thickness (BWT) assessment, the distance between the hyperechogenic mucosa and the hyperechogenic adventitia is measured. For detrusor wall thickness (DWT) assessment, the only measurement needed is the hypoechogenic detrusor sandwiched between the hyperechogenic mucosa and adventitia [82].

A significant correlation between BWT and pressure flow studies (PFS) parameters has been reported. A threshold value of 5 mm at the anterior bladder wall with a bladder filling of 150 mL was best at differentiating between patients with or without BOO [83]. DWT at the anterior bladder wall with a bladder filling ≥ 250 mL (threshold value for BOO ≥ 2 mm) has a PPV of 94% and a specificity of 95%, achieving 89%

agreement with PFS [64]. Threshold values of 2.0, 2.5, or 2.9 mm for DWT in patients with LUTS is able to identify 81%, 89%, and 100% of patients with BOO, respectively [84].

All studies found that BWT or DWT measurements have a higher diagnostic accuracy for detecting BOO than Q_{\max} or Q_{ave} of free uroflowmetry, measurements of PVR, prostate volume, or symptom severity. One study could not demonstrate any difference in BWT between patients with normal urodynamics, BOO or detrusor overactivity; however, the study did not use a specific bladder filling volume for measuring BWT [85]. Disadvantages of the method include the lack of standardisation, and lack of evidence to indicate which measurement (BWT/DWT) is preferable [86]. Measurement of BWT/DWT is therefore not recommended for the diagnostic work-up of men with LUTS.

Ultrasound-estimated bladder weight (UEBW) may identify BOO with a diagnostic accuracy of 86% at a cut-off value of 35 g [87, 88]. Severe LUTS and a high UEBW (≥ 35 g) are risk factors for prostate/BPH surgery in men on α -blockers [89]. The role of BWT, DWT and UEBW as a non-invasive alternative to PFS in the assessment of male LUTS or BOO is under evaluation.

3B.10.5 Voiding cysto-urethrogram

Voiding cysto-urethrogram (VCUG) is not recommended in the routine diagnostic work-up of men with LUTS, but it may be useful for the detection of vesico-ureteral reflux, bladder diverticula, or urethral pathologies in selected patients. Retrograde urethrography may additionally be useful for the evaluation of urethral strictures where suspected.

3B.11 Urethrocystoscopy

Patients with a history of microscopic or gross haematuria, urethral stricture, associated risk factors, or bladder cancer, who present with LUTS, should undergo urethrocystoscopy during diagnostic evaluation.

Shoukry et al. evaluated 122 patients with LUTS using uroflowmetry and urethrocystoscopy [90]. The pre-operative Q_{\max} was normal in 25% of 60 patients who had no bladder trabeculation, 21% of 73 patients with mild trabeculation and 12% of 40 patients with marked trabeculation on cystoscopy. All 21 patients who presented with diverticula had an 'obstructive' Q_{\max} .

Anikwe showed that there was no significant correlation between the degree of bladder trabeculation (graded from I to IV), and the pre-operative Q_{\max} value in 39 symptomatic men aged 53-83 years [91]. The largest study published on this issue examined the relation of urethroscopic findings to urodynamic studies in 492 elderly men with LUTS [92]. The authors noted a correlation between cystoscopic appearance (grade of bladder trabeculation and urethral occlusion) and urodynamic indices, detrusor overactivity and low compliance. It should be noted, however, that BOO was present in 15% of patients with normal cystoscopic findings, while 8% of patients had no obstruction, even in the presence of severe trabeculation [92].

Recommendation	LE	GR
Urethrocystoscopy should be performed in men with LUTS to exclude suspected bladder or urethral pathology and/or prior to minimally invasive/surgical therapies if the findings may change treatment.	3	B

LUTS = lower urinary tract symptoms.

3B.12 Urodynamics

In male LUTS, the most widespread invasive urodynamic techniques employed are filling cystometry and PFS. The major goal of urodynamics is to explore the functional mechanisms of LUTS and to identify risk factors for adverse outcomes (for informed/shared decision-making). Most terms and conditions (e.g. detrusor overactivity, low compliance, BOO/BPO, detrusor underactivity) are defined by urodynamic investigation.

3B.12.1 Diagnosing bladder outlet obstruction

PFS are the basis for the definition of BOO, which is characterised by increased detrusor pressure and decreased urinary flow rate during voiding. BOO/BPO has to be differentiated from detrusor underactivity (DUA), which signifies decreased detrusor pressure during voiding in combination with decreased urinary flow rate [2].

Urodynamic testing may also identify detrusor overactivity, which is a urodynamic observation characterised by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked. Overactive bladder is diagnosed from the patient's symptoms, not urodynamic testing, based on the presence of urgency, usually with increased daytime frequency and nocturia [2]. Studies have described an association between BOO and DO [93, 94]. In men with LUTS attributed to BPE, DO was present in 61% and independently associated with BOO grade and ageing [93].

The prevalence of DUA in men with LUTS is 11-40% [95, 96]. Detrusor contractility does not appear to decline in long-term BOO and surgical relief of BOO does not improve contractility [97, 98].

There are no published RCTs in men with LUTS and possible BPO that compare the standard practice investigation (uroflowmetry and PVR measurement) with PFS, but one such study is ongoing in the UK.

Due to the invasive nature of the test, a urodynamic investigation is generally only offered if conservative treatment has failed. The Guidelines Panel attempted to identify specific indications for PFS based on age, findings from the other diagnostic tests, and previous treatments. The Panel allocated a different degree of obligation for PFS in men > 80 years and men < 50 years, which may reflect the lack of evidence. In addition, there was no consensus whether PFS should or may be performed when considering surgery in men with bothersome predominantly voiding LUTS and $Q_{\max} > 10\text{ mL/s}$, although the Panel recognised that with $Q_{\max} < 10\text{ mL/s}$, BOO is likely and PFS are not necessarily needed.

Patients with neurological disease, including those with previous radical pelvic surgery should be assessed according to the EAU Guidelines on Neuro-Urology [99].

3B.12.2 Videourodynamics

Videourodynamics provides additional anatomical information and is primarily recommended if there is uncertainty regarding mechanisms of LUTS.

3B.12.3 Non-invasive pressure-flow testing

The penile cuff method, in which flow is interrupted to estimate isovolumetric bladder pressure), shows promising data, with good test/retest repeatability [100] and interobserver agreement [101], and a nomogram has been derived [102]. A method in which flow is not interrupted is also under investigation [103].

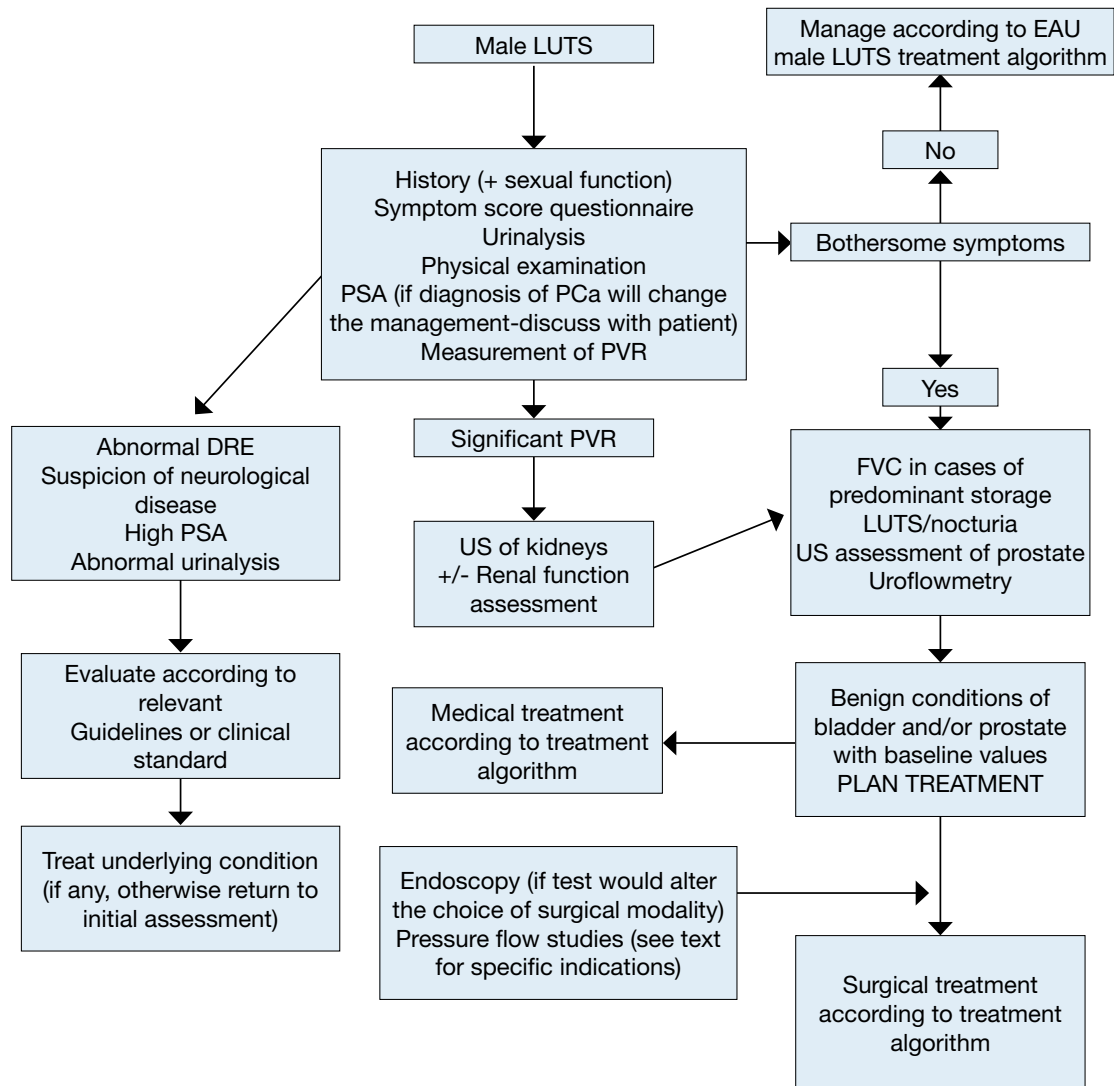

The data generated with the external condom method [104] correlates with invasive PFS in a high proportion [105]. Resistive index [106] and prostatic urethral angle [107] have also been proposed, but are still experimental.

Recommendations	LE	GR
PFS should be performed only in individual patients for specific indications prior to surgery or when evaluation of the underlying pathophysiology of LUTS is warranted.	3	B
PFS should be performed in men who have had previous unsuccessful (invasive) treatment for LUTS.	3	B
When considering surgery, PFS may be used for patients who cannot void > 150 mL.	3	C
When considering surgery in men with bothersome, predominantly voiding LUTS, PFS may be performed in men with a PVR > 300 mL.	3	C
When considering surgery in men with bothersome, predominantly voiding LUTS, PFS may be performed in men aged > 80 years.	3	C
When considering surgery in men with bothersome, predominantly voiding LUTS, PFS should be performed in men aged < 50 years.	3	B

LUTS = lower urinary tract symptoms; PFS = pressure-flow studies, PVR = post-void residual.

Figure 2: Assessment algorithm of LUTS in men aged 40 years or older

Readers are strongly recommended to read the full text that highlights the current position of each test in detail.

3C DISEASE MANAGEMENT

3C.1 Conservative treatment

3C.1.1 Watchful waiting

Many men with LUTS are not troubled enough by their symptoms to need drug treatment or surgical intervention. All men with LUTS should be formally assessed prior to any allocation of treatment in order to establish symptom severity and to differentiate between men with uncomplicated (the majority) and complicated LUTS. Watchful waiting (WW) is a viable option for many men with non-bothersome LUTS as few will progress to acute urinary retention and complications (e.g. renal insufficiency or stones) [108, 109], and others can remain stable for years [110]. In one study, approximately 85% of men with mild LUTS were stable on WW at one year [111].

A large study comparing WW and transurethral resection of the prostate (TURP) in men with moderate LUTS showed the surgical group had improved bladder function (flow rates and PVR volumes), especially in those with high levels of bother; 36% of WW patients crossed over to surgery within five years, leaving 64% doing well in the WW group [112, 113]. Increasing symptom bother and PVR volumes are the strongest predictors of clinical failure. Men with mild-to-moderate uncomplicated LUTS who are not too troubled by their symptoms are suitable for WW.

3C.1.2 Behavioural and dietary modifications

It is customary for this type of management to include the following components:

- education (about the patient's condition);
- reassurance (that cancer is not a cause of the urinary symptoms);
- periodic monitoring;
- lifestyle advice [110, 111, 114, 115] such as:
 - reduction of fluid intake at specific times aimed at reducing urinary frequency when most inconvenient (e.g. at night or when going out in public);
 - avoidance/moderation of intake of caffeine or alcohol, which may have a diuretic and irritant effect, thereby increasing fluid output and enhancing frequency, urgency and nocturia;
 - use of relaxed and double-voiding techniques;
 - urethral milking to prevent post-micturition dribble;
 - distraction techniques such as penile squeeze, breathing exercises, perineal pressure, and mental tricks to take the mind off the bladder and toilet, to help control storage symptoms;
 - bladder retraining that encourages men to hold on when they have sensory urgency to increase their bladder capacity and the time between voids;
 - reviewing the medication and optimising the time of administration or substituting drugs for others that have fewer urinary effects (these recommendations apply especially to diuretics);
 - providing necessary assistance when there is impairment of dexterity, mobility, or mental state;
 - treatment of constipation.

There now exists evidence (LE: 1b) that self-management as part of WW reduces both symptoms and progression [114, 115] (Table 1). Men randomised to three self-management sessions in addition to standard care had better symptom improvement and QoL than men treated with standard care only for up to a year [115].

Table 1: Self-management as part of watchful waiting reduces symptoms and progression [115]

Trial	Duration (weeks)	Treatment	Patients	IPSS	Q _{max} (mL/s)	PVR (mL)	LE
Brown et al. (2007) [115]	52	Standard care	67	-1.3	-	-	1b
		Standard care plus self-management	73	-5.7 * †	-	-	

IPSS = International Prostate Symptom Score; PVR = post-void residual urine; Q_{max} = maximum urinary flow rate during free uroflowmetry. *significant compared with standard care ($p < 0.05$); †significant compared with baseline ($p < 0.05$).

3C.1.3 Practical considerations

The components of self-management have not been individually studied. The above components of lifestyle advice have been derived from formal consensus methodology [116]. Further research in this area is required.

Recommendations	LE	GR
Men with mild symptoms are appropriate for watchful waiting.	1b	A
Men with LUTS should always be offered lifestyle advice prior to or concurrent with treatment.	1b	A

LUTS = lower urinary tract symptoms.

3C.2 Pharmacological management

3C.2.1 α_1 -Adrenoceptor antagonists (α_1 -blockers)

Mechanism of action: α_1 -blockers aim to inhibit the effect of endogenously released noradrenaline on smooth muscle cells in the prostate and thereby reduce prostate tone and BOO [117]. However, α_1 -blockers have little effect on urodynamically determined bladder outlet resistance [118], and treatment-associated improvement of LUTS is correlated only poorly with obstruction [119]. Thus, other mechanisms of action may be relevant.

α_1 -adrenoceptors located outside the prostate (e.g. urinary bladder and/or spinal cord) and α_1 -adrenoceptor subtypes (α_{1B} - or α_{1D} -adrenoceptors) may play a role as mediators of effects. α_1 -adrenoceptors in blood vessels, other non-prostatic smooth muscle cells, and the central nervous system may mediate adverse events.

α_1 -blockers currently available include: alfuzosin hydrochloride (alfuzosin); doxazosin mesylate (doxazosin); silodosin; tamsulosin hydrochloride (tamsulosin); terazosin hydrochloride (terazosin). α_1 -blockers exist in different formulations (see supplementary online material Table S.3). Although different formulations

result in different pharmacokinetic and tolerability profiles, the overall clinical impact of the different formulations is modest.

Efficacy: Indirect comparisons between α_1 -blockers and limited direct comparisons demonstrate that all α_1 -blockers have a similar efficacy in appropriate doses [120]. Effects take a few weeks to develop fully, but significant efficacy over placebo can occur within hours to days [121].

Controlled studies show that α_1 -blockers typically reduce IPSS by approximately 30-40% and increase Q_{\max} by approximately 20-25% (Table 2). However, considerable improvements also occurred in the corresponding placebo arms [48, 121]. In open-label studies, an IPSS improvement of up to 50% and Q_{\max} increase of up to 40% were documented [48, 121].

α_1 -blockers are able to reduce both storage and voiding LUTS. Prostate size does not affect α_1 -blocker efficacy in studies with follow-up periods of < 1 year, but α_1 -blockers do seem to be more efficacious in patients with smaller prostates (< 40 mL) in longer-term studies [122-125]. α_1 -blocker efficacy is similar across age groups [121]. α_1 -blockers neither reduce prostate size nor prevent acute urinary retention in long-term studies [49, 123-125]; some patients must therefore be treated surgically. Nevertheless, IPSS reduction and Q_{\max} improvement during α_1 -blocker treatment appears to be maintained over at least four years.

Tolerability and safety: Tissue distribution, subtype selectivity, and pharmacokinetic profiles of certain formulations may contribute to the tolerability profile of specific drugs. The most frequent adverse events of α_1 -blockers are asthenia, dizziness and (orthostatic) hypotension. Vasodilating effects are most pronounced with doxazosin and terazosin, and are less common for alfuzosin and tamsulosin [141]. Patients with cardiovascular comorbidity and/or vaso-active co-medication may be susceptible to α_1 -blocker-induced vasodilatation [142]. In contrast, the frequency of hypotension with the α_{1A} -selective blocker silodosin is comparable with placebo [132].

An adverse ocular event termed intra-operative floppy iris syndrome (IFIS) was reported in 2005, affecting cataract surgery [143]. A meta-analysis on IFIS after alfuzosin, doxazosin, tamsulosin or terazosin exposure showed an increased risk for all the α_1 -blockers [144]. However, the odds-ratio for IFIS was much higher for tamsulosin. It appears prudent not to initiate α_1 -blocker treatment prior to scheduled cataract surgery, and the ophthalmologist should be informed about α_1 -blocker use.

A systematic review concluded that α_1 -blockers do not adversely affect libido, have a small beneficial effect on erectile function, but sometimes cause abnormal ejaculation [145]. Originally, abnormal ejaculation was thought to be retrograde, but more recent data demonstrate that it is due to a decrease or absence of seminal fluid during ejaculation, with young age being an apparent risk factor. Abnormal ejaculation has been observed more frequently with tamsulosin and silodosin than with other α_1 -blockers [10, 146]. Silodosin has the highest incidence of abnormal ejaculation; however, efficacy seems to be increased in patients experiencing abnormal ejaculation [146, 147].

Practical considerations: Alpha1-blockers are often considered the first-line drug treatment of male LUTS because of their rapid onset of action, good efficacy, and low rate and severity of adverse events. Ophthalmologists should be informed about α_1 -blocker use prior to cataract surgery.

Recommendation	LE	GR
Alpha1-blockers can be offered to men with moderate-to-severe LUTS.	1a	A

Table 2: Randomised, placebo-controlled trials with α_1 -blockers in men with LUTS

3C.2.2 5 α -Reductase inhibitors

Mechanism of action: Androgen effects on the prostate are mediated by dihydrotestosterone (DHT), which is converted from testosterone by the enzyme 5 α -reductase, a nuclear-bound steroid enzyme [148]. Two isoforms of this enzyme exist:

- 5 α -reductase type 1, with minor expression and activity in the prostate but predominant activity in extraprostatic tissues, such as skin and liver.
- 5 α -reductase type 2, with predominant expression and activity in the prostate.

Two 5 α -reductase inhibitors (5-ARIs) are available for clinical use: dutasteride and finasteride (see supplementary online material Table S.4). Finasteride inhibits only 5 α -reductase type 2, whereas dutasteride inhibits 5 α -reductase types 1 and 2 with similar potency (dual 5-ARI). However, the clinical role of dual inhibition remains unclear. 5-ARIs act by inducing apoptosis of prostate epithelial cells [149] leading to prostate size reduction of about 18-28% and circulating PSA levels of about 50% after 6-12 months of treatment [150]. Mean prostate volume reduction and PSA decrease may be even more pronounced after long-term treatment. Continuous treatment reduces the serum DHT concentration by approximately 70% with finasteride and 95% with dutasteride. However, prostate DHT concentration is reduced to a similar level (85-90%) by both 5-ARIs.

Efficacy: Clinical effects relative to placebo are seen after a minimum treatment duration of at least 6-12 months. After two to four years of treatment, 5-ARIs improve IPSS by approximately 15-30%, decrease prostate volume by approximately 18-28%, and increase Q_{\max} by approximately 1.5-2.0 mL/s in patients with LUTS due to prostate enlargement (Table 3) [49, 124, 125, 151-157]. Indirect comparison between individual studies and one direct comparative trial indicate that dutasteride and finasteride are equally effective in the treatment of LUTS [150, 158]. Symptom reduction depends on initial prostate size.

Finasteride may not be more efficacious than placebo in patients with prostates < 40 mL [159]. However, dutasteride seems to reduce IPSS, prostate volume, and the risk of acute urinary retention, and to increase Q_{\max} even in patients with prostate volumes of between 30 and 40 mL at baseline [160, 161]. Comparative studies with α_1 -blockers and a recent meta-analysis have demonstrated that 5-ARIs reduce LUTS slower and that finasteride is less effective than either doxazosin or terazosin, but equally effective compared with tamsulosin [49, 151, 152, 162, 163]. A long-term trial with dutasteride in symptomatic men with prostate volumes >30 mL and increased risk for disease progression showed that dutasteride reduced LUTS at least as much as, or even more effectively than, the α_1 -blocker tamsulosin [124, 157, 164]. The greater the baseline prostate volume (or serum PSA concentration), the faster and more pronounced the symptomatic benefit of dutasteride.

5 α -reductase inhibitors, but not α_1 -blockers, reduce the long-term (>1 year) risk of acute urinary retention (AUR) or need for surgery [49, 155, 165]. In the Proscar Long-Term Efficacy and Safety Study, finasteride treatment reduced the relative risk of AUR by 57%, and surgery by 55% at four years, compared with placebo [155]. In the Medical Therapy of Prostatic Symptoms (MTOPS) study, a significant reduction in the risk of AUR and surgery in the finasteride arm compared with placebo was reported (68% and 64%, respectively) [49].

A pooled analysis of randomised trials with two-year follow-up data, reported that treatment with finasteride significantly decreased the occurrence of AUR by 57%, and surgical intervention by 34%, in moderately symptomatic LUTS [166]. Dutasteride has also demonstrated efficacy in reducing the risks for AUR and BPH-related surgery. Open-label trials have demonstrated relevant changes in urodynamic parameters [167, 168].

Table 3: Randomised trials with 5 α -reductase inhibitors in men with LUTS and benign prostatic enlargement due to BPH

IPSS = International Prostate Symptom Score; Q_{max} = maximum urinary flow rate (free uroflowmetry)

[†]Boyarski score; ^asignificant compared with baseline (indexed wherever evaluated); ^bsignificant compared with placebo/active control.

Tolerability and safety: The most relevant adverse effects of 5-ARIs are related to sexual function, and include reduced libido, erectile dysfunction and, less frequently, ejaculation disorders such as retrograde ejaculation, ejaculation failure, or decreased semen volume [49, 125, 150]. The incidence of sexual dysfunction and other adverse events is low and even decreased with trial duration. Gynaecomastia (with breast or nipple tenderness) develops in 1-2% of patients.

Data from two trials on prostate cancer chemoprevention (the Prostate Cancer Prevention Trial and the Reduction by Dutasteride of Prostate Cancer Events trial) found a higher incidence of high-grade cancers in the 5-ARIs arms [169, 170]. Although no causal relationship with high-grade prostate cancer has been proven, men taking a 5-ARI should be followed-up regularly using serial PSA testing and any confirmed PSA increase should be evaluated accordingly.

Practical considerations: Treatment with 5-ARIs should be considered in men with moderate-to-severe LUTS and an enlarged prostate (> 40 mL) and/or elevated PSA concentration (> 1.4-1.6 ng/mL). Due to the slow onset of action, they are suitable only for long-term treatment (years). Their effect on the serum PSA concentration needs to be considered for prostate cancer screening. 5 α -reductase inhibitors (finasteride) might reduce blood loss during transurethral prostate surgery, probably due to their effects on prostatic vascularisation [171].

Recommendations	LE	GR
5 α -Reductase inhibitors can be offered to men who have moderate-to-severe LUTS and an enlarged prostate (>40 mL).	1b	A
5 α -Reductase inhibitors can prevent disease progression with regard to acute urinary retention and the need for surgery.	1b	A

LUTS = lower urinary tract symptoms.

3C.2.3 Muscarinic receptor antagonists

Mechanism of action: The detrusor is innervated by parasympathetic nerves whose main neurotransmitter is acetylcholine, which stimulates muscarinic receptors (M-cholinoreceptors) on the smooth muscle cells.

Muscarinic receptors are also present on other cell types, such as bladder urothelial cells, epithelial cells of the salivary glands, or the peripheral or central nervous system. Five muscarinic receptor subtypes (M1-M5) have been described, of which M2 and M3 are predominant in the detrusor. M2 are more numerous, but the M3 subtype is functionally more important in bladder contractions in healthy humans [172, 173]. Antimuscarinic effects might also be induced or modulated through other cell types, such as the bladder urothelium or by central nervous system [174, 175].

The following muscarinic receptor antagonists are licensed for treating overactive bladder/storage symptoms (see supplementary online material Table S.5): darifenacin hydrobromide (darifenacin); fesoterodine fumarate (fesoterodine); oxybutynin hydrochloride (oxybutynin); propiverine hydrochloride (propiverine); solifenacin succinate (solifenacin); tolterodine tartrate (tolterodine); trospium chloride.

Efficacy: Antimuscarinics were mainly tested in females in the past, because it was believed that LUTS in men are caused by the prostate, so should be treated with prostate-specific drugs. However, there is no scientific data for that assumption [176]. A sub-analysis of an open-label trial of OAB patients showed that age but not gender has an impact on urgency, frequency, or urgency incontinence [177].

Efficacy of tolterodine or fesoterodine were tested as single agents in men with OAB in the absence of BOO (Table 4) [178-184]. Most trials lasted only 12 weeks. Four post hoc analyses of large RCTs on the treatment of OAB in women and men without presumed BOO were performed focusing only on the men [179, 181, 184, 185]. Tolterodine can significantly reduce urgency incontinence, daytime or 24-hour frequency, urgency-related voiding, and improve patient perception of treatment benefit. Solifenacin significantly improved mean patient perception of bladder condition scores, mean OAB questionnaire scores, and overall perception of bladder problems. Fesoterodine improved micturition frequency, urgency episodes, and urgency urinary incontinence (UUI) episodes. In open-label trials with tolterodine, daytime frequency, nocturia, UUI, and IPSS were significantly reduced compared with baseline values after 12-25 weeks [180, 183].

In the Tolterodine and Tamsulosin in Men with LUTS including OAB: Evaluation of Efficacy and Safety study, men who received tolterodine monotherapy saw improvement only in urgency incontinence, but not urgency, IPSS (total or storage subscore), or the overall percentage of patients reporting treatment benefit compared with placebo [182].

A further analysis showed that men with PSA levels of <1.3 ng/mL (smaller prostates) might profit more from antimuscarinic drugs [186]. Two other studies found a positive effect of antimuscarinics in patients with OAB and concomitant BPO [183, 187]. In a small RCT without placebo, propiverine improved frequency and urgency episodes [187]. In an open-label study, tolterodine decreased 24-hour micturition, nocturia and American Urological Association Symptom Index scores [183].

Table 4: Trials with antimuscarinic drugs only in elderly men with LUTS, predominantly with OAB symptoms

IPSS = International Prostate Symptom Score.

^asignificant compared with baseline ($p < 0.01$; indexed wherever evaluated); ^bsignificant compared with placebo ($p < 0.05$); ^csignificant compared with fesoterodine 4 mg ($p < 0.05$).

Tolerability and safety: Antimuscarinic drug trials generally show approximately 3-10% withdrawals, which is similar to placebo. Drug-related adverse events include dry mouth (up to 16%), constipation (up to 4%), micturition difficulties (up to 2%), nasopharyngitis (up to 3%), and dizziness (up to 5%).

Increased PVR in men without BOO is minimal and similar to placebo. Nevertheless, fesoterodine 8 mg showed higher PVRs (+20.2 mL) than placebo (-0.6 mL) or fesoterodine 4 mg (+9.6 mL) [179]. Incidence of urinary retention in men without BOO was similar to placebo for tolterodine (0-1.3% vs. 0-1.4%). With fesoterodine 8 mg, 5.3% had symptoms, which was higher than placebo or fesoterodine 4 mg (both 0.8%). These symptoms appeared during the first two weeks of treatment and mainly affected men aged 66 years or older.

Antimuscarinics theoretically might decrease bladder strength, and hence might be associated with PVR urine or urinary retention. A 12-week safety study on men with mild to moderate BOO showed that tolterodine increased the PVR (49 mL vs. 16 mL) but not acute urinary retention (3% in both arms) [188]. The urodynamic effects included larger bladder volumes at first detrusor contraction, higher maximum cystometric capacity, and decreased bladder contractility index. Q_{max} was unchanged. This trial indicated that short-term treatment with antimuscarinics in men with BOO is safe [188].

Practical considerations: Not all antimuscarinics have been tested in elderly men, and long-term studies on the efficacy of muscarinic receptor antagonists in men of any age with LUTS are not yet available. In addition, only patients with low PVR volumes at baseline were included in the studies. These drugs should therefore be prescribed with caution, and regular re-evaluation of IPSS and PVR urine is advised.

Recommendations	LE	GR
Muscarinic receptor antagonists may be used in men with moderate-to-severe LUTS who mainly have bladder storage symptoms.	1b	B
Caution is advised in men with BOO.	4	C

BOO = bladder outlet obstruction; LUTS = lower urinary tract symptoms.

3C.2.4 Phosphodiesterase 5 inhibitors

Mechanism of action: PDE type 5 inhibitors (PDE5Is) increase intracellular cyclic guanosine monophosphate, thus reducing smooth muscle tone of the detrusor, prostate and urethra. Nitric oxide and PDEs might also alter reflex pathways in the spinal cord and neurotransmission in the urethra, prostate, or bladder [189]. Moreover, chronic treatment with PDE5I seems to increase blood perfusion and oxygenation in the LUT [190]. Finally, PDE5Is could reduce chronic inflammation in the prostate and bladder [191].

Available drugs: Although clinical trials of several selective oral PDE5Is have been conducted in men with LUTS, only tadalafil (5 mg once daily) has been licensed for the treatment of male LUTS.

Efficacy: Several RCTs have demonstrated that PDE5Is reduce IPSS, storage and voiding LUTS, and QoL (Table 5). Q_{max} increases in a dose-dependent fashion, but is not significantly different from placebo in most trials. In a meta-analysis, PDE5Is were found to improve IPSS and International Index of Erectile Function (IIEF) score, but not Q_{max} [192].

Tadalafil 5 mg reduces IPSS by 22-37% (Table 5), and improvement may be seen within a week of initiation of treatment [193]; the maximum trial (open label) duration was 52 weeks [194]. A subgroup analysis of pooled data demonstrated a significant reduction in LUTS, regardless of baseline severity, age, previous use of α -blockers or PDE5Is, total testosterone level or predicted prostate volume [195]. In a study on sexually active men ≥ 45 years with comorbid LUTS/BPH and ED, tadalafil improved both conditions [196]. Another analysis showed a small but significant increase in Q_{max} , and no significant effect on PVR [197].

The combination of PDE5Is and α -blockers has also been evaluated. A meta-analysis of 5 RCTs (two studies with tadalafil 20 mg, two with sildenafil 25 mg, and one with vardenafil 20 mg), showed that combination therapy significantly improved IPSS score (-1.8), IIEF score (+3.6) and Q_{max} (+1.5 mL/s) compared with α -blockers alone [192]. However, only tadalafil 5 mg has been licensed in the context of LUTS management, so data on combinations of PDE5Is and other LUTS medications are considered insufficient.

Tolerability and safety: Reported adverse effects (AEs) in RCTs comparing the effect of all PDE5Is vs. placebo in men with LUTS include: flushing, gastroesophageal reflux, headache, dyspepsia, back pain and nasal congestion [192]. Discontinuation rate due to AEs for tadalafil is 2.0% [198] and do not differ by age, LUTS severity, testosterone levels, and prostate volume in the pooled data analyses [195].

PDE5Is are contraindicated in patients using nitrates, the potassium channel opener, nicorandil, or α_1 -blockers doxazosin or terazosin. They are also contraindicated in patients who have unstable angina pectoris, have had a recent myocardial infarction (<3 mo) or stroke (<6 mo), myocardial insufficiency (New York Heart Association stage >2), hypotension, poorly controlled blood pressure, significant hepatic or renal insufficiency, or if anterior ischaemic optic neuropathy with sudden loss of vision is known or was reported after previous use of PDE5Is.

Practical considerations: To date, only tadalafil 5 mg once daily has been officially licensed for the treatment of male LUTS with or without erectile dysfunction. The meta-analysis of PDE5Is suggested that younger men with low body mass index and more severe LUTS profit the most from treatment with PDE5Is [192].

Long-term experience with tadalafil in men with LUTS is limited to one trial [194], and therefore conclusions about its efficacy or tolerability >1 year are not possible. There is limited information about reduction of prostate size and none about disease progression.

Recommendations	LE	GR
PDE5Is reduce moderate-to-severe (storage and voiding) LUTS in men with or without erectile dysfunction.	1a	A
Only tadalafil (5 mg once daily) has been licensed for the treatment of male LUTS in Europe.		

LUTS = lower urinary tract symptoms; PDE5I = phosphodiesterase type 5 inhibitors.

3C.2.5 **Plant extracts - phytotherapy**

Mechanism of action: Herbal drug preparations are made of roots, seeds, pollen, bark, or fruits of a single plant (mono-preparations); others combine the extracts of two or more plants to one pill (combination preparations). The most widely used plants are: *Cucurbita pepo* (pumpkin seeds), *Hypoxis rooperi* (South African star grass), *Pygeum africanum* (bark of the African plum tree), *Secale cereale* (rye pollen), *Serenoa repens* (syn. *Sabal serrulata*; berries of the American dwarf palm, saw palmetto) and *Urtica dioica* (roots of the stinging nettle).

Possible relevant compounds include phytosterols, β -sitosterol, fatty acids, and lectins [206]. In vitro, plant extracts can have anti-inflammatory, anti-androgenic and oestrogenic effects; decrease sexual hormone binding globulin; inhibit aromatase, lipoxygenase, growth factor-stimulated proliferation of prostatic cells, α -adrenoceptors, 5 α -reductase, muscarinic cholinceptors, dihydropyridine receptors and vanilloid receptors; and neutralise free radicals [206-208]. These effects have not been confirmed in vivo, and the precise mechanisms of action of plant extracts remain unclear.

Efficacy: The extracts of the same plant produced by different companies do not necessarily have the same biological or clinical effects and so the effects of one brand cannot be extrapolated to others [209]. Batches from the same producer might contain different concentrations of active ingredients [210]. Thus the pharmacokinetic properties can vary significantly.

Table 6 presents the trials with the highest LE for each plant extract. In general, no phytotherapeutic agent has been shown to reduce prostate size, and no trial has proven a reduction of BOO or a decrease in disease progression. Analysis of each drug class can be found in the supplementary online material (see www.uroweb.org/guidelines).

Cochrane meta-analyses suggest that a) men treated with *Pygeum africanum* were twice as likely to report symptom improvement, b) men treated with *Secale cereale* were twice as likely to benefit from therapy compared to placebo and c) *Serenoa repens* was not superior to placebo, finasteride, or tamsulosin for IPSS (similar levels of IPSS improvements in trials with finasteride or tamsulosin might be interpreted as treatment equivalence) [211-213].

IPSS = International Prostate Symptom Score; n = number of patients; NA = not available; NS = not significant; PVR = post-void residual urine; Q_{max} = maximal urinary flow rate (free uroflowmetry); RR = relative risk.

[†]absolute values; ^asignificant reduction compared with placebo/comparison treatment arm (p < 0.05);

^bin favour of plant extract.

Tolerability and safety: Side-effects during phytotherapy are generally mild and comparable to placebo. Serious adverse events were not related to study medication. Gastrointestinal complaints were the most commonly reported. In formulations with *Hypoxis rooperi*, erectile dysfunction appeared in 0.5% of patients.

Practical considerations: Phytotherapeutic agents are a heterogeneous group and may contain differing concentrations of the active ingredient(s). Hence, meta-analyses do not seem to be justified and results of any analyses have to be interpreted with caution.

Recommendations: The Guidelines Panel have not made any specific recommendations on phytotherapy for the treatment of male LUTS because of product heterogeneity, limited regulatory framework, and methodological limitations of the published trials and meta-analyses.

3C.2.6 Vasopressin analogue - desmopressin

Mechanism of action: The antidiuretic hormone arginine vasopressin (AVP) regulates water homeostasis. It controls urine production through the V2 receptor in the renal collecting ducts. AVP increases water re-absorption and urinary osmolality, while decreasing water excretion and total urine volume. AVP also has V1 receptor mediated vasoconstrictive/hypertensive effects and a very short serum half-life, so is unsuitable as a treatment for nocturnal polyuria.

Desmopressin is a synthetic analogue of AVP with high V2 receptor affinity and antidiuretic properties, but has no relevant V1 receptor affinity or hypertensive effects. Desmopressin may be used by intravenous infusion, nasal spray, tablet or 'melt' formulation. Nasally or orally administered desmopressin is rapidly absorbed, and excreted 55% unchanged by the kidneys [222]. Desmopressin has been used for more than 30 years for diabetes insipidus or primary nocturnal enuresis, and it is approved in most European countries for the treatment of nocturia secondary to nocturnal polyuria in adults (see supplementary online material Table S.6).

Efficacy: Desmopressin significantly reduced nocturnal diuresis by approximately 0.6-0.8 mL/min (-40%), decreased the number of nocturnal voids by approximately 0.8-1.3 (-40%), and extended the time until the first nocturnal void by 1.6-2.1 hours (Table 7). Furthermore, desmopressin significantly reduced night-time urine volume, and the percentage of urine volume excreted at night [223-225].

A meta-analysis found that desmopressin significantly reduced the overall number of nocturnal voids and increased hours of undisturbed sleep. However, the RCTs were conducted in heterogeneous populations, using varied dosages [23].

The clinical effects of desmopressin were more pronounced in patients with more severe nocturnal polyuria and normal bladder capacity at baseline. The 24-hour diuresis remained unchanged during desmopressin treatment [226]. The clinical effects were stable over a follow-up period of 10-12 months and returned to baseline values after cessation of the trial [223].

Tolerability and safety: The most frequent adverse events in short-term (up to three weeks) and long-term studies (12 months) were headache, nausea, diarrhoea, abdominal pain, dizziness, dry mouth and hyponatraemia (serum sodium concentration of <130 mmol/L). Peripheral oedema (2%) and hypertension (5%) were reported in the long-term treatment trial [223].

Hyponatraemia, not necessarily associated with symptoms, occurs in 5.0-7.6% of patients soon after treatment initiation [235, 236]. The risk of developing hyponatraemia significantly increases with age (odds ratio 1.16 per year of age), lower serum sodium concentration at baseline (odds ratio 0.76), and higher basal 24-hour urine volume per bodyweight (odds ratio 1.09) [235]. The risk of hyponatraemia in patients < 65 years is < 1%; for older patients with normal sodium concentration it is 8%, but it is up to 75% in old patients with low sodium concentration at baseline [235]. A recent subanalysis suggests that oral doses of 50-100µg desmopressin (melt) are safe in men [237].

At the time of treatment initiation or dose change, older men with normal values of serum sodium should be monitored by Na⁺ measurement at day three and day seven of treatment, and one month later. If serum sodium concentration has remained normal and no dose adjustment is intended, Na⁺ should be monitored every three to six months thereafter [238]. Patients should be informed about the symptoms of hyponatraemia, (headache, nausea or insomnia).

Practical considerations

Desmopressin is taken once daily before sleeping. Because the optimal dose differs between patients, desmopressin treatment should be initiated at a low dose (0.1 mg/day) and may be gradually increased up to a dosage of 0.4 mg/day every week until maximum efficacy is reached. Patients should avoid drinking fluids at least one hour before and for eight hours after dosing. In men aged 65 years or older, desmopressin should not be used if the serum sodium concentration is below normal.

Recommendation	LE	GR
Vasopressin analogue can be used for the treatment of nocturia due to nocturnal polyuria.	1b	A

3C.2.7 Emerging therapies

3C.2.7.1 Beta-3 agonists

Mechanism of action: Beta-3 adrenoceptors are the predominant beta receptors expressed in the smooth muscle cells of the detrusor and their stimulation is thought to induce detrusor relaxation.

Efficacy: Mirabegron 50 mg is the first clinically available beta-3 agonist and has received approval for use in adults with OAB. Mirabegron has undergone extensive evaluation in three 12-week, RCTs conducted in Europe, Australia, and North America and a further 12-month randomised, double-blind, active treatment-controlled, study in OAB patients [239-242]. Mirabegron at daily doses of 25, 50, and 100 mg demonstrated significant efficacy in treating the symptoms of OAB, including micturition frequency, urgency incontinence, and urgency and also patient perception of treatment benefit.

Tolerability and safety: The most common treatment-related adverse events in the mirabegron groups were hypertension, urinary tract infection, headache and nasopharyngitis [239-242]. The proportion of patients with

dry mouth and constipation in the mirabegron groups was notably lower than reported in RCTs of other OAB agents or of the active control tolterodine [239]. Evaluation of urodynamic parameters in men with combined BOO and OAB concluded that mirabegron did not adversely affect voiding urodynamic parameters compared to placebo in terms of Q_{\max} , detrusor pressure at maximum flow and bladder contractility index [243].

Practical considerations: Long-term studies on the efficacy and safety of mirabegron in men of any age with LUTS are not yet available. Studies on the use of mirabegron in combination with other pharmacotherapeutic agents for male LUTS are still pending.

Recommendation	LE	GR
Beta-3 agonists may be used in men with moderate-to-severe LUTS who have predominantly bladder storage symptoms.	1b	B

LUTS = lower urinary tract symptoms.

3C.2.8 Combination therapies

3C.2.8.1 α_1 -blockers + 5 α -reductase inhibitors

Mechanism of action: Combination therapy consists of an α_1 -blocker (Section 3C.2.1) together with a 5-ARI (Section 3C.2.2). The α_1 -blocker exhibits clinical effects within hours or days, whereas the 5-ARI needs several months to develop significant clinical efficacy. Finasteride has been tested in clinical trials with alfuzosin, doxazosin or terazosin, and dutasteride with tamsulosin.

Efficacy: Several studies have investigated the efficacy of combination therapy against an α_1 -blocker, 5-ARI or placebo alone (Table 8). Initial studies with follow-up periods of 6-12 months demonstrated that the α_1 -blocker was superior to finasteride in symptom reduction, whereas combination was not superior to α_1 -blocker alone [151, 152, 162]. In studies with a placebo arm, the α_1 -blocker was consistently more effective than placebo, but finasteride was not. Data at one year in the MTOPS study (published but not specifically analysed for this timepoint), showed similar results [49].

Long-term data (4 years) from MTOPS, and Combination of Avodart and Tamsulosin (CombAT) trials showed that combination treatment is superior to monotherapy for symptoms and Q_{\max} , and superior to α -blocker in reducing the risk of acute urinary retention or need for surgery [49, 124, 125].

The CombAT study demonstrated that combination treatment is superior to either monotherapy for symptoms and flow rate starting from month nine, and superior to α_1 -blocker for acute urinary retention and the need for surgery after month eight [125]. The different results between the CombAT and MTOPS trials may reflect different inclusion and exclusion criteria, rather than the specific drugs used.

Discontinuation of the α_1 -blocker after six to nine months of combination therapy was investigated by an RCT and an open-label multicentre trial [244, 245]. The first trial evaluated the combination of tamsulosin with dutasteride and the impact of tamsulosin discontinuation after six months [244], with almost three-quarters of patients reporting no worsening of symptoms. However, patients with severe symptoms (IPSS > 20) at baseline may benefit from longer combination therapy.

A more recently published trial evaluated the symptomatic outcome of finasteride monotherapy at three and nine months after discontinuation of nine-month combination therapy [245]. LUTS improvement after combination therapy was sustained at three months (IPSS difference 1.24) and nine months (IPSS difference 0.44). However, the main limitations of the studies include the short duration and the short follow-up period after discontinuation.

In both the MTOPS and CombAT trials, combination therapy was superior to monotherapy in preventing clinical progression as defined by an IPSS increase of at least four points, acute urinary retention, urinary tract infection, incontinence, or an increase in creatinine >50%. The MTOPS study found that the risk of long-term clinical progression (primarily due to increasing IPSS) was reduced by 66% with combined therapy (vs placebo) and to a greater extent than with either finasteride or doxazosin monotherapy (34% and 39%, respectively) [49]. In addition, finasteride (alone or in combination), but not doxazosin, significantly reduced both the risks of AUR and the need for BPH-related surgery over the four-year study. In the CombAT study, combination therapy reduced the relative risks of AUR by 68%, BPH-related surgery by 71%, and symptom deterioration by 41% compared with tamsulosin, after four years [246].

Note: [124] and [125] reflect different timepoints in the same study

IPSS = International Prostate Symptom Score; Q_{max} = maximum urinary flow rate (free uroflowmetry).

^asignificant compared with baseline (indexed wherever evaluated); ^bsignificant compared with placebo;

^csignificant compared with α -blocker monotherapy; ^dsignificant compared with 5 α -reductase inhibitor monotherapy.

Tolerability and safety: Adverse events for both drug classes have been reported with combination treatment [49, 124, 125]. The adverse events observed during combination treatment were typical of α_1 -blockers and 5-ARIs. The frequency of adverse events was significantly higher for combination therapy.

Practical considerations: Compared with α_1 -blockers or 5-ARI monotherapy, combination therapy results in a greater improvement in LUTS and increase in Q_{max} , and is superior in prevention of disease progression. However, combination therapy is also associated with more adverse events. Combination therapy should therefore be prescribed primarily in men who have moderate-to-severe LUTS and are at risk of disease progression (higher prostate volume, higher PSA concentration, advanced age, etc.). Combination therapy should only be used when long-term treatment (more than 12 months) is intended; this issue should be discussed with the patient before treatment. Discontinuation of the α_1 -blocker after six months might be considered in men with moderate LUTS.

Recommendation	LE	GR
Combination treatment with an α_1 -blocker together with a 5 α -reductase inhibitor can be offered to men with troublesome moderate-to-severe LUTS, enlarged prostate and reduced Q_{max} (men likely to develop disease progression).	1b	A

Q_{max} = maximum urinary flow rate.

3C.2.8.2 α_1 -blockers + muscarinic receptor antagonists

Mechanism of action: Combination treatment consists of an α_1 -blocker together with an antimuscarinic aiming to antagonise both α_1 -adrenoceptors and muscarinic receptors. The possible combinations have not all been tested in clinical trials yet.

Efficacy: Several RCTs and prospective studies investigated combination therapy, lasting 4-12 weeks, either as an initial treatment in men with OAB and presumed BPO or as a sequential treatment for storage symptoms persisting while on an α_1 -blocker [182, 183, 246-253] (Table 9). One trial used the α_1 -blocker naftopidil (not registered in most European countries) with and without antimuscarinics [254].

Combination treatment is more efficacious in reducing urgency, UII, voiding frequency, nocturia, or IPSS compared with α_1 -blockers or placebo alone, and improves QoL [182]. Symptom improvement is higher regardless of PSA concentration, whereas tolterodine alone improved symptoms mainly in men with a serum PSA of < 1.3 ng/mL [186].

Persistent LUTS during α_1 -blocker treatment can be reduced by the additional use of an antimuscarinic, especially when detrusor overactivity is demonstrated [183, 246, 250, 253]. Two systematic reviews of the efficacy and safety of antimuscarinics in men suggested that combination treatment provides significant benefit [255, 256].

ER = extended-release; IPSS = International Prostate Symptom Score.

^asignificant compared with baseline ($p \leq 0.05$, indexed wherever evaluated); ^bsignificant reduction compared with placebo ($p < 0.05$); [‡]persisting LUTS during α_1 -blocker treatment (add-on approach).

Tolerability and safety: Adverse events of both drug classes are seen with combined treatment using

α_1 -blockers and antimuscarinics. The commonest side-effect is xerostomia. Some side-effects (e.g. xerostomia or ejaculation failure) may show increased incidence which cannot simply be explained by summing the incidence with the drugs used separately. Increased PVR may be seen, but is usually not clinically significant, and risk of AUR is low [255, 256].

A recent RCT investigated safety in terms of maximum detrusor pressure and Q_{\max} for solifenacin (6 mg or 9 mg) with tamsulosin in men with LUTS and BOO compared with placebo [257]. The combination therapy was not inferior to placebo for the primary urodynamic variables; Q_{\max} was increased versus placebo [257].

Practical considerations: Class effects are likely to underlie efficacy and QoL using an α_1 -blocker and antimuscarinic. Trials used mainly storage symptom endpoints, were of short duration, and included only men with low PVR volumes at baseline. Therefore, measuring PVR is recommended during combination treatment.

Recommendations	LE	GR
Combination treatment with an α_1 -blocker together with a muscarinic receptor antagonist may be used in patients with troublesome moderate-to-severe LUTS if relief of storage symptoms has been insufficient with monotherapy with either drug.	1b	B
Combination treatment should be prescribed with caution in men who may have BOO.	2b	B

BOO = bladder outlet obstruction; LUTS = lower urinary tract symptoms.

3C.3 Surgical treatment

3C.3.1 Transurethral resection of the prostate and transurethral incision of the prostate

Mechanism of action: Transurethral resection of the prostate (TURP) removes tissue from the transition zone of the gland. Transurethral incision of the prostate (TUIP) involves incising the bladder outlet without tissue removal. This technique may replace TURP in selected cases, especially in prostate sizes ≤ 30 mL without a middle lobe.

Efficacy: In a recent analysis of 20 contemporary RCTs with a maximum follow-up of 5 years, TURP resulted in a substantial mean Q_{\max} improvement (+162%), a significant reduction in IPSS (-70%), QoL score (-69%), and PVR (-77%) [258]. TURP delivers durable outcomes as shown by studies with a follow-up of 8-22 years. There are no similar data on durability for any other surgical treatment for BPO [259]. One study with a mean follow-up of 13 years reported a significant and sustained decrease in most symptoms and improvement in urodynamic parameters. Failures were associated with detrusor underactivity rather than re-development of BPO [98].

Table 10 presents RCTs comparing TUIP with TURP [260-267]. A meta-analysis of short- and long-term data from 10 RCTs found similar LUTS improvements and lower but insignificant improvements in Q_{\max} for TUIP [262]. In this meta-analysis, an upper limit of prostate size was reported as an entry criterion for eight studies with five < 30 ml and three < 60 ml.

A second prostatic operation, usually re-TURP, has been reported at a constant annual rate of approximately 1-2%. A review analysing 29 RCTs found a re-treatment rate of 2.6% after a mean follow-up of 16 months [268]. In a large-scale study of 20,671 men, the overall re-treatment rates (re-TURP, urethrotomy and bladder neck incision) were 5.8%, 12.3%, and 14.7%, at 1, 5, and 8 years of follow-up, respectively, and the respective incidence of re-TURP was 2.9%, 5.8% and 7.4% [269]. A meta-analysis of six trials showed that re-operation was more common after TUIP (18.4%) than after TURP (7.2%) [262].

Tolerability and safety: Peri-operative mortality and morbidity have decreased over time, but the latter remains considerable (0.1% and 11.1%, respectively) [270]. The possibility of increased long-term mortality compared to open surgery [271] has not been verified [272-274]. Data from 20,671 TURPs and 2,452 open prostatectomies (OP) showed that short- and long-term procedural mortality was similar (0.7% vs. 0.9% at 90 days, 2.8% vs. 2.7% at 1 year, 12.7% vs. 11.8% at 5 years, 20% vs. 20.9% at 8 years) and that the 8-year myocardial infarction rates were identical (4.8 vs. 4.9%) [269].

The risk of TUR-syndrome decreased to $< 1.1\%$ [268, 275]. No case has been recorded after TUIP. Data from 10,654 TURPs reported bleeding requiring transfusion in 2.9% [270]. The risk after TUIP is negligible [268]. Similar results for TURP complications were reported by an analysis of contemporary RCTs using TURP as a comparator: bleeding requiring transfusion 2% (0-9%), TUR-syndrome 0.8% (0-5%), AUR 4.5% (0-13.3%), clot retention 4.9% (0-39%), and urinary tract infection (UTI) 4.1% (0-22%) [258]. Long-term complications comprise urinary incontinence (1.8% after TUIP vs. 2.2% after TURP), urinary retention and UTIs, bladder neck contracture (BNC) (4.7% after TURP), urethral stricture (3.8% after TURP vs. 4.1% after TUIP), retrograde ejaculation (65.4% after TURP vs. 18.2% after TUIP), and erectile dysfunction (6.5% after TURP) [268].

Practical considerations: TURP and TUIP are effective treatments for moderate-to-severe LUTS secondary to BPO. The choice should be based primarily on prostate volume (< 30 mL and 30-80 mL suitable for TUIP and TURP, respectively). No studies on the optimal cut-off value exist but the complication rates increase with prostate size [270]. The upper limit for TURP is mostly suggested as 80 mL (based on Panel expert opinion, under the assumption that this limit depends on the surgeon's experience, resection speed, and choice of resectoscope size).

3C.3.1.1 Modifications of TURP: bipolar TURP

Mechanism of action: Bipolar TURP (B-TURP) addresses a major limitation of monopolar TURP (M-TURP) by allowing performance in normal saline. Contrary to M-TURP, in B-TURP systems, the energy does not travel through the body to reach a skin pad. Bipolar circuitry is completed locally; energy is confined between an active (resection loop) and a passive pole situated on the resectoscope tip ("true" bipolar systems) or the sheath ("quasi-" bipolar systems). Prostatic tissue removal is identical to M-TURP. However, B-TURP requires less energy/voltage because there is a smaller amount of interpolated tissue. Energy from the loop is transmitted to the saline solution, resulting in excitation of sodium ions to form a plasma; molecules are then easily cleaved under relatively low voltage enabling resection. During coagulation, heat dissipates within vessel walls, creating a sealing coagulum and collagen shrinkage. The various bipolar devices available differ in the way in which current flow is delivered [276, 277].

Efficacy: B-TURP is the most widely and thoroughly investigated alternative to M-TURP. Results from > 40 RCTs [278] have been reported, of which around half have been pooled in three RCT-based meta-analyses [258, 279, 280]. Early pooled results concluded that no clinically relevant differences exist in short-term (up to 12 months) efficacy (IPSS, QoL score and Q_{max}) [280]. Subsequent meta-analyses supported these conclusions [258, 279], though trial quality was generally poor. Data from RCTs with a follow-up of 12-60 months show no differences in efficacy parameters (Table 11) [281-287].

Tolerability and safety: Early pooled results concluded that no differences exist in short-term (up to 12 months) US/BNC rates, but B-TURP is preferable due to a more favourable perioperative safety profile (elimination of TUR-syndrome; lower clot retention/blood transfusion rates; shorter irrigation, catheterisation, and possibly hospitalisation times) [280]. Subsequent meta-analyses supported these conclusions [258, 279]. However, trial quality is relatively poor and limited follow-up may cause under-reporting of late complications, such as urethral stricture/BNC [280]. Data from individual RCTs with a follow-up of 12-60 months showed no differences in urethral stricture/BNC rates (Table 11) [281-288].

A focused RCT using the erectile function domain of the IIEF (IIEF-ED) showed that M-TURP and B-TURP have a similar effect [289]. A comparative evaluation of the effects on the overall sexual function, quantified with IIEF-15 showed no differences between B-TURP and M-TURP at 12 months of follow-up (erection, orgasmic function, sexual desire, intercourse satisfaction, overall satisfaction) [290].

Practical considerations: B-TURP offers an attractive alternative to M-TURP in patients with moderate-to-severe LUTS secondary to BPO, with similar efficacy but lower peri-operative morbidity [280]. The duration of improvements with B-TURP was documented in a number of RCTs with a follow-up of >12 months. Mid-term results (up to 5 years) of B-TURP showed that safety and efficacy are comparable to M-TURP. The choice of B-TURP should be based on equipment availability, surgeon's experience, and patient's preference.

Recommendations	LE	GR
M-TURP is the current surgical standard procedure for men with prostate sizes of 30-80 mL and bothersome moderate-to-severe LUTS secondary of BPO. M-TURP provides subjective and objective improvement rates superior to medical or minimally invasive treatments.	1a	A
The morbidity of M-TURP is higher than for drugs or other minimally invasive procedures.	1a	A
B-TURP achieves short- and mid-term results comparable with M-TURP.	1a	A
B-TURP has a more favourable peri-operative safety profile compared with M-TURP.	1a	A
TUIP is the surgical therapy of choice for men with prostate sizes <30 mL, without a middle lobe, and bothersome moderate-to-severe LUTS secondary to BPO.	1a	A

BPO = benign prostatic obstruction; B-TURP = bipolar TURP; LUTS = lower urinary tract symptoms; M-TURP = monopolar TURP; TUIP = transurethral incision of the prostate; TURP = transurethral resection of the prostate.

Table 10: Efficacy and safety of transurethral resection of the prostate or transurethral incision of the prostate in level 1 trials at 12 or 24 months. Absolute and relative changes compared to baseline with regard to symptoms (Madson-Iverson or IPSS) and maximum urinary flow rate

BNC = bladder neck contracture; B-TURP = bipolar TURP; IPSS = International Prostate Symptom Score; M-TURP = monopolar TURP; Q_{max} = maximum urinary flow rate; TURP = transurethral resection of the prostate; US = urethral stricture.

^a = significantly different compared to baseline; NA = not available.

3C.3.2 Open prostatectomy

Mechanism of action: OP is the oldest surgical treatment for moderate-to-severe LUTS secondary to BPO. Obstructive adenomas are enucleated using the index finger, approaching from within the bladder (Freyer procedure) or through the anterior prostatic capsule (Millin procedure).

Efficacy: OP is the treatment of choice for large glands (> 80-100 mL). Three RCTs showed that Holmium laser enucleation of the prostate (HoLEP) and photoselective vaporisation of the prostate (PVP) lead to similar outcomes compared to OP in men with large glands (> 70 mL) at a significantly lower complication rate [291-293]. The results of OP studies are summarised in Table 12. OP reduces LUTS by 63-86% (12.5-23.3 IPSS points), improves QoL score by 60-87%, increases mean Q_{max} by 375% (+16.5-20.2 mL/s), and reduces PVR by 86-98% [291-295]. Efficacy is maintained for > 5 years [291, 293, 295] (Table 12).

Tolerability and safety: Mortality has decreased significantly during the past two decades (< 0.25%) [294]. The estimated transfusion rate is about 7-14% [291, 294, 295]. Long-term complications include urinary incontinence (up to 10%), BNC and US (about 6%) [291-293, 296].

Practical considerations: OP is the most invasive but also the most effective and durable procedure for the treatment of LUTS/BPO. In the absence of an endourological armamentarium and a holmium laser, OP is the surgical treatment of choice for men with prostates > 80 mL.

Recommendations	LE	GR
OP or holmium laser enucleation are the first choice of surgical treatment in men with prostate sizes > 80 mL and bothersome moderate-to-severe LUTS secondary to BPO needing surgical treatment.	1b	A
OP is the most invasive surgical method with significant morbidity.	1b	A

BPO = benign prostatic obstruction; LUTS = lower urinary tract symptoms; OP = open prostatectomy.

Table 12: Results of OP studies for treating BPH-LUTS or BPO

Studies	Duration (weeks)	Patients (n)	Change in symptoms (IPSS)		Change in Q_{max}		Change in PVR		Change in prostate volume		LE
			Absolute	%	mL/s	%	mL	%	mL	%	
Kuntz et al. 2008 [291]	260	32	-18.2	86	21.4	677	-287	98			1b

BPH = benign prostatic hyperlasia; BPO = benign prostatic obstruction; IPSS = International Prostate Symptom Score; LE = level of evidence; LUTS = lower urinary tract symptoms; n = number of patients; OP = open prostatectomy; PVR = post-void residual urine; Q_{max} = maximum urinary flow rate (free uroflowmetry).

3C.3.3 Transurethral microwave therapy

Mechanism of action: Microwave thermotherapy works by emitting microwave radiation through an intra-urethral antenna to deliver heat into the prostate. Tissue is destroyed by being heated at temperatures above cytotoxic thresholds (> 45°C) (coagulation necrosis). The heat may also cause apoptosis and denervation of α -receptors, thereby decreasing the smooth muscle tone of the prostatic urethra.

Conceptually, transurethral microwave therapy (TUMT) devices are all similar in delivering microwave energy with some type of feedback system, differing mainly in the design of the urethral applicator. This can have a significant effect on the heating profile [297]. There is also variation in the catheter construction, cooling systems, treatment time, and monitoring of TUMT effects [298].

Efficacy: A systematic review assessed therapeutic efficacy in different devices/software, including Prostatron (Prostatsoft 2.0 and 2.5) and ProstaLund Feedback (Table 13) [299]. It was concluded that TUMT was less effective than TURP in reducing LUTS. Symptom score after TUMT decreased by 65% in 12 months, compared to 77% after TURP. TURP achieved a greater Q_{max} improvement (119% vs. 70%) [299].

A pooled analysis of three studies (two RCTs and one open label) of ProstaLund Feedback TUMT (PLFT) with 12-month follow-up showed the responder rate was 85.3% and 85.9% after PLFT and TURP, respectively [300]. IPSS showed a subjective, non-inferior improvement with PLFT [300]. However, one-sided 95% CI analysis showed that PLFT non-inferiority did not reach the predetermined level, even though both improved Q_{max} significantly.

One RCT compared TUMT with terazosin [301]. After 18 months' follow-up, treatment failure in terazosin-treated patients (41%) was significantly greater compared to TUMT (5.9%), with TUMT achieving a greater improvement in IPSS and Q_{max} [302].

Previously, urinary retention was considered a contraindication for TUMT. Nowadays, LE:2b studies have reported an 80-93% success rate for TUMT, defined as the percentage of patients who regained their ability to void spontaneously [303-305]. However, these studies had a short follow-up (≤ 12 months), which makes it difficult to estimate the durability of TUMT outcome in patients with retention. In a study with a longer follow-up, treatment failure was 38% in the retention group, with a cumulative risk of 59% at 5 years [306].

An RCT-based systematic review estimated re-treatment rates [299] (though the trials had different follow-up periods) of 0.075 vs. 0.010 re-treatments per person per year for TUMT and TURP, respectively.

A multicentre RCT with follow-up of 5 years compared TUMT (PLFT; the Core-Therm device) and TURP. No significant differences were found in Q_{max} and IPSS. After TUMT, 10% needed additional treatment, vs. 4.3% after TURP. These data suggest clinical results obtained with PLFT-TUMT were comparable to TURP at five years. Most durability studies have a high attrition rate; in this study, less than half of the patients were analysed at 4-5 years. In addition, patients who remained in the study were likely to represent the best data (responders).

Tolerability and safety: Treatment is well tolerated, although most patients experience perineal discomfort and urinary urgency, and require pain medication for therapy. Pooled morbidity data comparing TUMT and TURP have been published [299, 300, 307]. In the Cochrane RCT-based systematic review, catheterisation time, dysuria/urgency and urinary retention rates were significantly less with TURP. Hospitalisation time, haematuria, clot retention, transfusion, TUR syndrome, and urethral stricture rates were significantly less for TUMT [299]. Sexual dysfunction and re-treatment rates for urethral stricture/BNC were higher after TURP.

Practical considerations: Endoscopy prior to TUMT is essential to identify the presence of a prostate middle lobe or an insufficient length of the prostatic urethra. Due to the low peri- and post-operative morbidity and lack of need for anaesthesia, TUMT is a true outpatient procedure, and an option for older patients, and those with comorbidities or anaesthesia risk [308]. Independent baseline parameters that predict an unfavourable outcome include small prostates, mild-to-moderate BPO, and a low amount of energy delivered during treatment [309]. However, predictive factors for particular devices cannot necessarily be applied to other systems

Recommendations	LE	GR
TUMT achieves symptom improvement comparable with TURP, but TUMT is associated with decreased morbidity and lower flow improvements.	1a	A
Durability is in favour of TURP, which has lower re-treatment rates compared to TUMT.	1a	A

TUMT = transurethral microwave therapy; TURP = transurethral resection of the prostate.

IPSS = International Prostate Symptom Score; LE = level of evidence; PVol = prostate volume; PVR = post-void residual urine; Q_{max} = maximum urinary flow rate (free uroflowmetry); QoL = quality of life; TUMT = transurethral microwave therapy; ^a = significant compared to baseline (indexed whenever evaluated); n = number of patients; NS = not significant; NA = not available.

3C.3.4 Transurethral needle ablation of the prostate

Mechanism of action: The transurethral needle ablation (TUNA™) device delivers low-level radiofrequency energy to the prostate via needles inserted transurethrally into the parenchyma under direct vision using an attachment to the standard cystoscope. The energy induces coagulation necroses in the transition zone resulting in prostate volume reduction and BPO reduction.

Efficacy: A meta-analysis of two RCTs, two non-randomised protocols and 10 single-arm studies showed that TUNA™ achieved a 50% decrease in IPSS and a 70% improvement in Q_{max} at 1 year [315], supported by a more recent meta-analysis of 35 studies (9 comparative, 26 non-comparative) [316]. TUNA™ significantly improved IPSS and Q_{max}, but compared to TURP these improvements were significantly lower at 12 months. TURP vs. TUNA™ differences in means were - 4.72 and 5.9 mL/sec for IPSS and Q_{max} respectively [316].

Clinical studies on the impact of TUNA™ on BPO [317, 318] showed a significant decrease in maximum detrusor pressure or detrusor pressure at Q_{max}, but a number of patients were still obstructed.

Most studies were short-to-midterm in duration, and there were concerns about the durability of effects. A study with 5 years' follow-up demonstrated symptomatic improvement in 58% and improved flow in 41%. However, 21% required additional treatment [319]. TUNA™ has a significantly higher re-treatment rate compared with TURP. The overall re-treatment rate after TUNA™ was 19% based on an analysis of 17 non-comparative studies [316].

Tolerability and safety: Post-operative urinary retention with a mean duration of 1-3 days is seen in 13-42% of patients; within 1 week, 90-95% of patients are catheter-free [320]. Storage LUTS are common for the first 4-6 weeks after intervention [321]. TUNA™ is associated with fewer adverse events compared to TURP, including mild haematuria, urinary infections, strictures, incontinence, ED, and ejaculation disorders [316].

Practical considerations: TUNA™ can be performed as a day-case procedure under local anaesthesia or sedation [320]. TUNA™ is unsuitable for prostates > 75 mL or isolated bladder neck obstruction. TUNA™ cannot effectively treat prostatic middle lobes. There is anecdotal evidence for TUNA™ in men receiving aspirin and anti-coagulants. TUNA™ can be performed as a day-case procedure and is associated with fewer side-effects than TURP (e.g. bleeding, ED, urinary incontinence). However, there are concerns about the durability of the effects achieved by TUNA™.

Recommendations	LE	GR
TUNA™ achieves symptom improvement comparable with TURP, but TUNA™ is associated with decreased morbidity and lower flow improvements.	1a	A
Durability is in favour of TURP with lower re-treatment rates compared to TUNA™.	1a	A

TUNA™ = transurethral needle ablation; TURP = transurethral resection of the prostate.

IPSS = International Prostate Symptom Score; LE = level of evidence; Q_{max} = maximum urinary flow rate;

PVR = post-void residual urine; TUNA™ = transurethral needle ablation; TURP = transurethral resection of the prostate.

^a = TURP significantly better compared with TUNA™.

3C.3.5 Laser treatments of the prostate

3C.3.5.1 Holmium laser enucleation and holmium laser resection of the prostate

Mechanism of action: The holmium:yttrium-aluminium garnet (Ho:YAG) laser (wavelength 2140 nm) is a pulsed solid-state laser that is absorbed by water and water-containing tissues. Tissue coagulation and necrosis are limited to 3-4 mm, which is enough to obtain adequate haemostasis [322]. Holmium laser resection of the prostate (HoLRP) or holmium laser enucleation of the prostate (HoLEP) result in BPO relief and, secondarily, in LUTS reduction.

Efficacy: In a meta-analysis of studies comparing HoLRP with TURP, no difference in symptom improvement could be detected at 6 or 12 months post operatively (Table 15) [323]. One RCT comparing TURP with HoLRP with a minimum follow-up of 4 years showed no difference in urodynamics after 48 months [324]. Three meta-analyses covering trials on HoLEP versus TURP found that symptom improvement was comparable or superior with HoLEP (Table 15) [325-327]. One RCT comparing photoselective vaporisation of the prostate (PVP)

and HoLEP in patients with prostates > 60 mL showed comparable symptom improvement but significantly higher flow rates and lower PVR volume after HoLEP [328]. Another RCT on HoLAP and 80-W PVP showed comparable functional improvement within a median follow-up of 71 months [329].

RCTs indicate that HoLEP is as effective as open prostatectomy for improving micturition in large prostates [291, 292], with similar re-operation rates after 5 years (5% vs. 6.7%, respectively) [291]. One RCT comparing HoLEP with TURP in a small number of patients who completed the 7-year follow-up found that the functional long-term results of HoLEP were comparable with TURP [330]. A retrospective study of HoLEP with the longest follow-up (up to 10 years, mean 62 months) reported durable functional results with low re-operation rates [331].

Tolerability and safety: Dysuria is the most common post-operative complication [322, 325]. Compared to TURP, HoLRP has shorter catheterisation and hospitalisation times [323, 332]. Potency, continence, and major morbidity at 48 months were identical between HoLRP and TURP [324]. Three meta-analyses found that HoLEP has a shorter catheterisation time and hospital stay, reduced blood loss, and fewer blood transfusions, but a longer operation time compared with TURP [325-327]. In a meta-analysis, no significant differences were noted between HoLEP and TURP for urethral stricture (2.6% vs. 4.4%), stress urinary incontinence (1.5% vs. 1.5%), and re-intervention (4.3% vs. 8.8%) [326]. HoLEP is superior to open prostatectomy for blood loss, catheterisation and hospitalisation time [291, 292].

HoLEP has been safely performed in patients using anticoagulant medications [333, 334]. In a study of 83 patients, blood transfusion was required in seven patients (8%) [335]. A retrospective study compared the safety results of HoLEP between 39 patients who were on anticoagulant therapy at the time of their surgery, and 37 controls [334]. No transfusions were required and bleeding complication rates were not significantly different [334]. Short-term studies showed that patients with urinary retention can be treated with HoLEP [336, 337].

The impact on ED and retrograde ejaculation is comparable between HoLEP and TURP/OP [292, 338]. Erectile function did not decrease from baseline in either group; three quarters of sexually active patients had retrograde ejaculation after HoLEP.

Practical considerations: Holmium laser operations are surgical procedures that require experience and relevant endoscopic skills. The experience of the surgeon was the most important factor affecting the overall occurrence of complications [333, 339].

3C.3.5.2 532 nm ("Greenlight") laser vaporisation of prostate

Mechanism of action: The kalium-titanyl-phosphate (KTP) and the lithium triborate (LBO) lasers work at a wavelength of 532 nm. Laser energy is absorbed by haemoglobin, but not by water. Vaporisation leads to immediate removal of prostatic tissue, relief of BPO, and reduction of LUTS. In 2014, three different Greenlight lasers were in use: the 80-W (KTP), 120-W HPS (LBO), and the 180-W XPS (LBO) laser systems. They differ in maximum power output, fibre design, and maximum energy application.

Efficacy: A meta-analysis of the nine available RCTs comparing PVP using the 80-W and 120-W lasers with TURP was performed in 2012 (Table 15) [340]. No differences were found in Q_{\max} and IPSS between PVP and TURP, but only three RCTs provided sufficient 12-month data to be included in the meta-analysis [341-343].

The longest RCT using the 80-W KTP laser has a follow-up of only 12 months [341]. A case series showed durable functional outcomes after the 80-W KTP laser, with an overall re-treatment rate of 8.9% at 5 years [344]. Another case series of 500 patients treated with the 80-W system with a mean follow-up of 30.6 months reported a re-treatment rate of 14.8% [345].

Significant improvements in voiding parameters at a follow-up of 12 months were demonstrated urodynamically [346]. The longest RCT comparing the 120-W HPS laser with TURP had a follow-up of 36 months and showed a comparable improvement in IPSS, Q_{\max} , and PVR [347]. Re-operation rate was higher after PVP (11% vs. 1.8%; $p = 0.04$) [347]. Similar improvement of IPSS, QoL, Q_{\max} , or urodynamic parameters was reported from two RCTs with a maximum follow-up of 24 months [342, 348].

A multicentre case series of the 180-W laser demonstrated comparable safety and symptom improvement compared with the former Greenlight laser systems [349].

Tolerability and safety: A meta-analysis of the RCTs comparing the 80-W and 120-W lasers with TURP showed a significantly longer operating time but shorter catheterisation time and length of hospital stay after PVP [340]. Blood transfusions and clot retention were less with PVP. No difference was noted in post-operative urinary retention, infection, meatal stenosis, urethral stricture, or bladder neck stenosis [340].

The Greenlight laser appears to be safe in high-risk patients under anticoagulation treatment [350-354]. In one study, anticoagulated patients had significantly higher rate of bladder irrigation (17.2%) compared

with Greenlight laser without taking anticoagulants (5.4%) [353]. Safety in patients with urinary retention, or prostates > 80 mL was shown in various prospective non-randomised trials [354-356].

The impact of Greenlight laser on sexual function seems to be similar to that of TURP. One RCT comparing TURP and Greenlight PVP reported no significant difference in the rate of retrograde ejaculation [357]. In addition, no difference was reported between OP/TURP and Greenlight PVP for erectile function [358, 359]. IIEF-5 scores are maintained after treatment. However, in patients with preoperative IIEF-5 >19, the post-operative IIEF-5 scores were significantly decreased at 6, 12, and 24 months [360].

Practical considerations: The evolution of the Greenlight laser from 80-W to 120-W and then to 180-W resulted in a wide variation in the degree of maturity of each laser therapy. Long-term results on 120-W and RCTs on 180-W are still pending.

3C.3.5.3 Diode laser vaporisation of the prostate

Mechanism of action: For prostate surgery, diode lasers with a wavelength of 940, 980, 1318, and 1470 nm (depending on the used semiconductor) are marketed for vaporisation and enucleation. Only a few have been evaluated in clinical trials [361].

Efficacy: Case series, and two comparative studies of a 980-nm diode laser and the 120 W HPS laser, are available [362-368]. IPSS, QoL, Q_{max} , and PVR improved significantly in all studies compared to baseline and were similar compared to 120-W HPS laser, at 6 and 12 months [362, 363]. However, RCTs and long-term follow up is lacking.

One RCT with a 12 month follow-up compared 980 nm diode laser with plasmakinetic enucleation and found equal clinical outcome (Table 15). Adverse events and catheter time favoured the diode laser group [369]. One small RCT with a 6 months' follow-up comparing laser enucleation using a 1318-nm diode laser with B-TURP reported similar efficacy and safety results (Table 15) [370]. Blood loss and hospitalisation time were in favour of laser enucleation.

Tolerability and safety: Two studies (980 nm) indicate high intraoperative safety, since no bleeding was reported, although anticoagulants or platelet aggregation inhibitors were taken in 24% and 52% [362, 363]. Post-operatively, a higher rate of dysuria occurs than with 120-W HPS laser [362, 363]. Fibre modifications led to a significant reduction [365]. In summary, high re-operation rates (20-33%) and persisting stress urinary incontinence (9.1%) were reported [362-364].

Practical considerations: Diode lasers lead to immediate improvements of LUTS due to BPO and provide good haemostatic properties. Based on the lack of RCTs and controversial data on the re-treatment rate, diode lasers cannot be recommended as a standard treatment option for BPO.

3C.3.5.4 Thulium:yttrium-aluminium-garnet laser (Tm:YAG)

Mechanism of action: In the Tm:YAG laser, a wavelength of 2013 nm is emitted in continuous-wave mode. The laser is primarily used in front-fire applications [361]. Different applications, ranging from vaporisation (ThuVaP), vaporessection (ThuVaRP), and enucleation (ThuVEP/ThuLEP: similar enucleating techniques) are published.

Efficacy: A major drawback is the limited number of RCTs. Maximum follow-up of 4 years (case control study) with cumulative re-operation rates of 6% reported [371]. One RCT and one non-RCT compared ThuVaRP with M-TURP [372, 373], while two RCTs comparing ThuVaRP and B-TURP were published recently [374, 375]. In summary, studies show comparable improvement of symptoms and voiding parameters. There are only a few case studies on ThuVEP showing a significant improvement in IPSS, Q_{max} , and PVR after treatment [376-379]. ThuLEP and HoLEP were compared in one RCT with 18-months of follow-up with comparable outcome in both arms (Table 15) [380].

Tolerability and safety: Thulium laser prostatectomy shows high intra-operative safety in RCTs [372, 374, 380], as well as in case series in patients with large prostates [376], anticoagulation or bleeding disorders [377]. Catheterisation time, hospital stay, and blood loss were shorter compared to TURP [372-374]. The rate of post-operative urethral strictures after ThuVaRP was 1.9%, the rate of bladder neck contracture was 1.8%, and re-operation rate was 0-7.1% during follow-up [372, 373, 381]. Urethral stricture after ThuVEP occurred in 1.6%, and the overall re-treatment rate was 3.4% (mean follow-up 16.5 months) [382]. No urethral and bladder neck strictures after ThuLEP were reported during the 18-month follow-up [380]. Recently a large series of complications after vapoenucleation reported adverse events in 31% of cases, with 6.6% complications > Clavien grade 2 [383].

Practical considerations: The limited number of RCTs and limited follow-up (up to 18 months) do not permit final conclusions regarding the long-term efficacy of thulium laser prostatectomy.

Recommendations	LE	GR
HoLEP and 532-nm laser vaporisation of the prostate are alternatives to TURP in men with moderate-to-severe LUTS due to BPO leading to immediate, objective, and subjective improvements comparable with TURP.	1a	A
The intermediate-term functional results of 532-nm laser vaporisation of the prostate are comparable with TURP.	1b	A
The long-term functional results of HoLEP are comparable with TURP/open prostatectomy.	1b	A
Diode laser operations lead to short-term objective and subjective improvement.	1b	B
ThuVaRP is an alternative to TURP for small- and medium-size prostates.	1b	A
ThuVEP leads to short-term objective and subjective improvement.	3	C
With regard to intra-operative safety and haemostatic properties, diode and thulium lasers appear to be safe.	3	C
With regard to intra-operative safety, 532-nm laser vaporisation is superior to TURP.	1b	A
532-nm laser vaporisation should be considered in patients receiving anticoagulant medication or with a high cardiovascular risk.	3	B

BPO = benign prostatic obstruction; HoLEP = holmium laser enucleation; LUTS = lower urinary tract symptoms; TURP = transurethral resection of the prostate; ThuVaRP = Tm:YAG vaporessection; ThuVEP = Tm:YAG vapoenucleation.

Table 15: Efficacy of different lasers for the treatment based on the highest-quality study for each of the treatment options. Absolute and relative changes compared to baseline, with regard to symptoms (AUA-SI/IPSS) and maximum urinary flow rate (Q_{\max})

AUA-SI = American Urological Association Symptom Index; B-TURP = bipolar transurethral resection of the prostate; HoLEP = holmium laser enucleation; HoLRP = holmium laser resection of the prostate; IPSS = International Prostate Symptom Score; KTP = greenlight laser vaporisation; NA = not available; Q_{max} = maximum urinary flow rate; TURP = transurethral resection of the prostate; ThuVaP = Tm:YAG vaporisation of the prostate; ThuVaRP = Tm:YAG vaporessection; ThuLEP = Tm:YAG laser enucleation of the prostate; ThuVEP = Tm:YAG vapoenucleation; WMD = weighted mean difference.

3C.3.6 Prostatic stents

Mechanism of action: The use of an endoprosthesis to preserve luminal patency is a well-established concept. Prostatic stents were primarily designed as an alternative to an indwelling catheter but have also been assessed as a primary treatment option in patients without significant comorbidities [384, 385].

A prostatic stent requires a functioning detrusor [386]. Permanent stents are biocompatible, which allows epithelialisation. Temporary stents do not epithelialise and may be either biostable or biodegradable. Temporary stents can provide short-term relief from BPO in patients temporarily unfit for surgery, or after minimally invasive treatment [386].

Efficacy: Several small case studies on a range of stents of different designs and materials have provided low level of evidence for their use. Table 16 describes the most important studies [384, 385, 387-390].

All studies observed a significant attrition rate. There is only one RCT that has compared two versions of a blind-placement prostatic stent (BPS) for BPO [391], and there have been no studies comparing stents with sham or other treatment modalities. The BPS system is temporary, with the difference between BPS-1 and BPS-2 being an additional 2 cm bulbar segment. This bulbar segment results in a significantly lower migration rate with BPS-2 (5%) compared with BPS-1 (85%) [391]. BPS-2 also resulted in superior symptom scores and voiding function, but only Q_{max} reached statistical significance [391].

The main representative of the permanent stents is the UroLume prosthesis. A systematic review identified 20 case series, with differing follow ups [392]. These trials reported relevant symptom improvement and Q_{max} increase [392].

The pooled data from studies with patients who were catheter dependent showed that 84% of patients (148/176) regained the ability to void spontaneously after UroLume treatment [392, 393].

The best data on non-epithelialising prostatic stents are provided by a systematic review of the efficacy of Memokath, a self-expanding metallic prostatic stent [394], which reduced IPSS by 11-19 points and increased Q_{max} by 3-11 mL/s [394].

Tolerability and safety: In general, stents are subject to misplacement, migration, and poor tolerability because of exacerbation of LUTS and encrustation [386]. The main immediate adverse events include perineal pain or bladder storage symptoms.

A systematic review of the UroLume reported a 16% failure rate within 12 months, mainly due to stent misplacement or migration (37%) or recurrent obstructive or irritative LUTS (14%). The overall failure rate at 5 years was 27% (50/188 stents) [392].

Practical considerations: Due to side effects and a high migration rate, prostatic stents have a limited role in the treatment of moderate-to-severe LUTS. Prostatic stents are an alternative to catheterisation for men who have (recurrent) urinary retention and are at high risk for surgery. Temporary stents can provide short-term relief from LUTS secondary to BPO in patients temporarily unfit for surgery or after minimally invasive treatment [386].

Recommendation	LE	GR
Prostatic stents are an alternative to catheterisation for men unfit for surgery.	3	C

Table 16: Efficacy of stents: key studies

Stent	n	Symptoms		Q _{max} (mL/s)		Failure rate (follow-up in months)	LE
		Pre-operative	Post-operative	Pre-operative	Post-operative		
Urolume (P) [384]	91	14.1	4.7	9.3	17.1	Overall	3
	44	R	4.6	R	13.7	15.5% (18)	
Memotherm (P) [387]	123	24.0	6.1*	7.4	16.1*	4% (48)	3
TITAN (P) [388]	85	15.9 ^a	9.33 ¹	8.59*	11.43 ¹	Overall	3
	59	18.0	5.21	R	11.34	19% (24)	
Spanner (T) [385]	30	22.3	7.1	8.2	11.6	0% (2)	3
Memokath (T-P) [389]	211	20.3	8.2 ²	NA	NA	23% (84)	3
Horizon Bell-shaped (T) [390]	108	22.0	15.0	9.1	9.6	46% (3)	3

Q_{max} = maximum urinary flow rate (free uroflowmetry); (P) = permanent stent; R = retention; (T) = temporary stent; NA = not available. * = immediately after insertion; ^a = Madsen score; ¹ = at 2 years; ² = at 3 months.

3C.3.7 Emerging operations

3C.3.7.1 Intraprostatic ethanol injections

Mechanism of action: Liquid dehydrated ethanol (95-98%) or ethanol gel is injected into the prostatic parenchyma either transurethrally [395-405], transperineally [400, 406, 407], or transrectally [400]. There is no consensus on the number or volume of injections, which depends on prostate volume, urethral length and/or presence of a median lobe, ranging from 2 to 25 mL in different studies. Most patients need an indwelling catheter after the procedure.

Efficacy: Several open trials without randomisation [395-407] have been published. Mean follow-up varied from 3 - 54 months, showing significant reduction in IPSS (-41% to -71%), PVR (-6% to -99%) and Q_{max} (+35% to +155%) and QoL (-47% to -60%). After an initial strong reduction in prostate volume (-4% to -45%), prostate size increased again by 1-2 years, although LUTS and Q_{max} remained improved [397]. No predictive efficacy parameter or dose-response relationship has been found [399, 404]. Little is known about the durability of clinical effects later than 1 year; one trial with a mean follow-up of 3 years showed a re-treatment rate of 41% [397]. A table with the key studies is available in the supplementary online material, Table S.7.

Tolerability and safety: Adverse events included: perineal or abdominal discomfort/pain, storage LUTS (≤ 40%), haematuria (≤ 40%), UTI or epididymitis, and retention. Less frequently reported (< 5%) were: decreased libido, retrograde ejaculation, urgency urinary incontinence, urethral stenosis, and ED. Two cases of bladder necrosis required cystectomy and urinary diversion were reported [399].

Practical considerations: The mechanism of action, patient selection, and application of ethanol have not been well investigated. In addition, severe adverse events occurred and long-term results are sparse. Intraprostatic ethanol injections are therefore regarded as experimental procedures for use only in trials.

Recommendation	LE	GR
Intraprostatic ethanol injections for men with moderate-to-severe LUTS secondary to BPO are still experimental and should be performed only in clinical trials.	3	C

BPO = benign prostatic obstruction; LUTS = lower urinary tract symptoms.

3C.3.7.2 Intra-prostatic botulinum toxin injections

Mechanism of action: Experience with intra-prostatic injections for the treatment of LUTS/BPO exists only for subtype BTX-A, which reduces LUTS by induction of apoptosis of prostatic (epithelial) cells leading to tissue atrophy and size reduction, and neuronal inhibition [408-412]. Down-regulation of α₁-adrenergic receptors may contribute to smooth muscle cell relaxation [408].

BTX-A can be injected into the prostatic parenchyma transperineally, transurethrally or transrectally. Different doses (100-300 U Botox™ or 300-600 U Dysport™) and dilutions (25-50 U Botox™/mL or 75 U Dysport™/mL) were used.

Efficacy: A review of 20 studies of varying evidence levels showed significant IPSS reduction in 13 studies [413], and significant Q_{max} improvement in 14. The reduction in prostate volume varied and was statistically significant in 18 studies. Durability of the effects ranged from 3 to 30 months [413].

The results from the largest placebo-controlled study of BTX-A (100 U, 200 U, and 300 U) however,

showed no significant difference in terms of IPSS, QoL, and Q_{\max} at week 12 [414]. Re-treatment rates with BTX-A were as high as 29% [415].

Tolerability and safety: BoNTA injections were well tolerated in all studies. The main reported complications after treatment included dysuria, haematuria, epididymitis, prostatitis, and grade 2-3 events (unspecified) among 35% of patients in the series [413]. In addition, patients may receive a transurethral catheter or perform clean intermittent catheterisation during the early post-operative period (1 week to 1 month) [416-418]. Intraprostatic injection of BoNTA in patients with BPE seem to have no impact on sexual function [413, 419].

Practical considerations: Initial studies indicated that BoNTA injections into the prostatic parenchyma seem to be a promising and rapid, minimally invasive treatment modality with low morbidity for patients who are refractory to medical treatment or in urinary retention. However, BTX-A has been injected into only a few patients, and all trials have a limited follow-up. Recent studies found no significant difference in the efficacy between BoNTA and placebo arm. Trials with a larger number of patients, randomisation against saline injections, drugs, TURP, or other minimally invasive treatments, systematic evaluation of doses and dilutions, and long-term follow-up are necessary to judge adequately the value of intraprostatic BoNTA injections in the context of other available medical or surgical treatments of LUTS/BPO.

Recommendation	LE	GR
Intraprostatic BTX injections for men with bothersome moderate-to-severe LUTS secondary to BPO or men in urinary retention are still experimental and should be performed only in clinical trials.	3	C

BPO = benign prostatic obstruction; BTX = botulinum toxin ; LUTS = lower urinary tract symptoms.

3C.3.7.3 Minimal invasive simple prostatectomy

Mechanism of action: The term minimal invasive simple prostatectomy (MISP) includes the laparoscopic simple prostatectomy (LSP) and robot-assisted simple prostatectomy (RASP). The technique for LSP was first described in 2002 [420], while the first RASP was reported in 2008 [421]. Both LSP and RASP are performed using different personalised techniques, developed based on the transcapsular (Millin) or transvesical (Freyer) techniques of open simple prostatectomy. An extraperitoneal approach is mostly used for LSP, while a transperitoneal is mostly used for RASP.

Efficacy: In 14 studies (11 case series and 3 comparative retrospective non-randomised case-control studies) with a total of 626 patients with large adenomas treated with LSP were analysed [422] (see supplementary online material Table S.8). Follow-up ranged from one to six months. IPSS, and Q_{\max} improved significantly in all studies compared to baseline and improvements were similar compared to OP in the comparative studies [422]. In one retrospective study with a mean follow-up of 30 months, improvement in IPSS and Q_{\max} remained durable [423].

Seven non-comparative case series on RASP ranging in size from 3-35 patients (in total 95 cases) are available [421, 424-429]. In all these series with a mean follow-up ranging from 1-13 months, a substantial postoperative improvement in urinary symptoms and Q_{\max} was observed. The studies with >10 patients are presented in the supplementary online material Table S.8.

Tolerability and safety: The systematic review on LSP demonstrated that the most frequent complications were bleeding requiring transfusion (5.6%), secondary haematuria/urinary retention requiring re-catheterisation (3%), urogenital tract infection (1.7%), reoperation (1.3%), urosepsis (0.9%), incontinence (0.9%), clot retention (0.9%) and urinary fistula (0.8%). In the three comparative studies, LSP was associated with less blood loss and a reduced irrigation requirement, a shorter catheterisation and hospitalisation time, at the expense of a longer operative time (see online Table S.8). In one study (not included in the systematic review) of 34 cases of single-port transvesical enucleation of the prostate (STEP), there were three complications during STEP (one death, one bowel injury and one haemorrhage) and five afterwards (four bleeding, one epididymo-orchitis) [430].

The studies on RASP mainly focused on the feasibility of the method and reported only major complications. There were two cases of conversion to OP (2.1%). Transfusion was required only in two patients in the earliest series [421, 429]. In addition two cases of urinary leak, one case of postoperative umbilical hernia and a case of a bladder neck stricture were reported [424, 426, 428]. Interestingly, one study reported no significant change in the preservation of sexual activity (mean Sexual Health Inventory: 12.7 pre-operatively vs. 12.5 at 6 months post-operatively) even if a persistent, severe urinary incontinence was recorded in 1 out of 9 patients [426].

Practical considerations: It should be underlined that the available evidence comes from case series and retrospective comparative studies from selected centers. High quality studies are needed to compare the efficacy, safety, and hospitalisation between MISP and both OP and endoscopic methods. Long-term outcomes, learning curve and cost of MISP should also be evaluated

Recommendation	LE	GR
MISP seems to be feasible in men with prostate sizes > 80 mL needing surgical treatment. Since more data are required, MISP remains under evaluation.	3	C

MISP = minimal invasive simple prostatectomy.

3C.3.7.4 Prostatic urethral lift

Mechanism of action: The prostatic urethral lift (PUL) represents a novel minimally invasive approach under local or general anaesthesia. Encroaching lateral lobes are compressed by small permanent suture-based implants delivered under cystoscopic guidance (Urolift®) resulting in an opening of the prostatic urethra that leaves a continuous anterior channel through the prostatic fossa ranging from bladder neck to the verumontanum.

Efficacy: The available studies on PUL are presented in the supplementary online material Table S.9 [431-435]. In general, PUL achieves a significant improvement in IPSS (-39% to -52%), Q_{max} (+32% to +59%) and QoL (-48% to -53%). There is only one RCT comparing PUL with sham [433]. The primary endpoint was met at 3 months with a 50% reduction in AUA-SI from 22.1 to 11.0 points and remained stable up to 12 months. Change for AUA-SI was 88% greater for the treatment group than sham control. Also Q_{max} increased significantly from 8.1 to 12.4 mL/s relative to baseline at 3 months and this result could still be confirmed at 12 months. The difference in clinical response for Q_{max} between both groups was of statistical significance. A relevant benefit with regard to PVR was not demonstrated compared to baseline nor relative to sham control.

A multicenter, prospective, non-randomised study on 64 patients evaluated effectiveness of PUL over 2 years [434]. At 2 weeks, IPSS improved by 42% and was maintained for 24 months. A similar therapeutic effect was also observed for Q_{max} which increased significantly by 45% from 8.3 to 12.0 mL/s after 2 weeks. This benefit was stable up to 2 years. However, at the 2 year follow-up, 20% of patients required additional treatment due to initial PUL failure [434].

Tolerability and safety: The most common complications reported post-operatively included haematuria (16-63%), dysuria (25-58%), pelvic pain (5-17.9%), urgency (7.1-10%), transient incontinence (3.6-16%), and urinary tract infection (2.9-11%). Most symptoms were mild to moderate in severity and resolved within two to four weeks after the procedure.

PUL seems to have no significant impact on sexual function. Evaluation of sexual function as measured by IIEF-5, Male Sexual Health Questionnaire-Ejaculatory Dysfunction, and Male Sexual Health Questionnaire-Bother in patients undergoing PUL showed that erectile and ejaculatory function were preserved (supplementary online material Table S.9) [431-435].

Practical considerations: Prostates up to 100 cm³ with lateral lobe obstruction are appropriate for this technique while an obstructed or protruding medial lobe cannot be effectively treated. Of note, resection or ablation of prostatic tissue is still possible without any limitation after initial treatment with the prostatic urethral lift. High quality studies are needed to compare the efficacy, safety and durability between PUL and established invasive treatments.

Recommendation	LE	GR
Prostatic urethral lift (Urolift™) leads to short-term objective and subjective improvement. RCTs with longer follow-up are needed to confirm these initial promising results	1b	B

RCT = randomised controlled trial.

3C.4 Patient selection

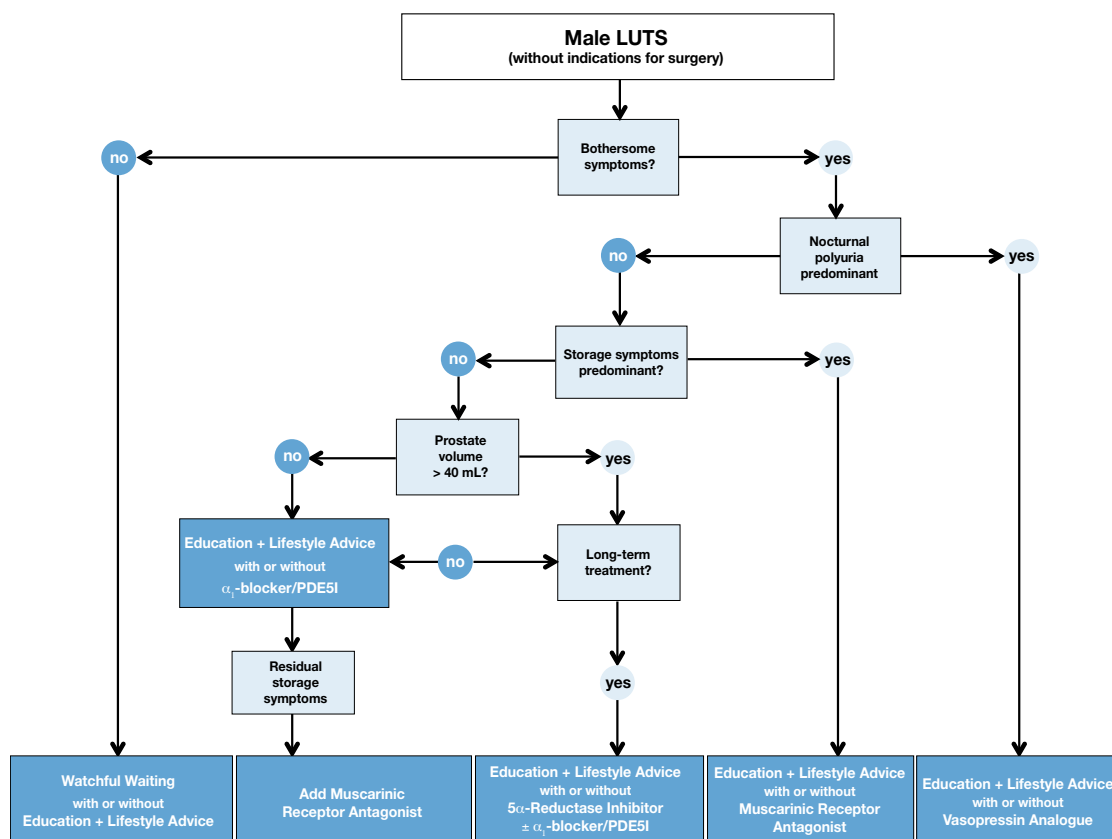

The choice of treatment depends on the assessed findings of patient evaluation, ability of the treatment to change the findings, treatment preferences of the individual patient, and the expectations to be met in terms of speed of onset, efficacy, side effects, QoL, and disease progression. A table which provides differential information about speed of onset and influence on basic parameters with conservative, medical or surgical treatment options is described in the supplementary online material, Table S.10.

Behavioural modifications, with or without medical treatments, are usually the first choice of therapy. Figure 3 provides a flow chart illustrating treatment choice according to evidence-based medicine and patient profiles.

Surgical treatment is usually required when patients have experienced recurrent or refractory urinary retention, overflow incontinence, recurrent UTIs, bladder stones or diverticula, treatment-resistant macroscopic haematuria due to BPH/BPE, or dilatation of the upper urinary tract due to BPO, with or without renal insufficiency (absolute operation indications, need for surgery).

Additionally, surgery is usually needed when patients have not obtained adequate relief from LUTS or PVR using conservative or medical treatments (relative operation indications). The choice of surgical technique depends on prostate size, comorbidities of the patient, ability to have anaesthesia, patients' preferences, willingness to accept surgery-associated specific side-effects, availability of the surgical armamentarium, and experience of the surgeon with these surgical techniques. An algorithm for surgical approaches according to evidence-based medicine and patient profile is provided in Figure 4.

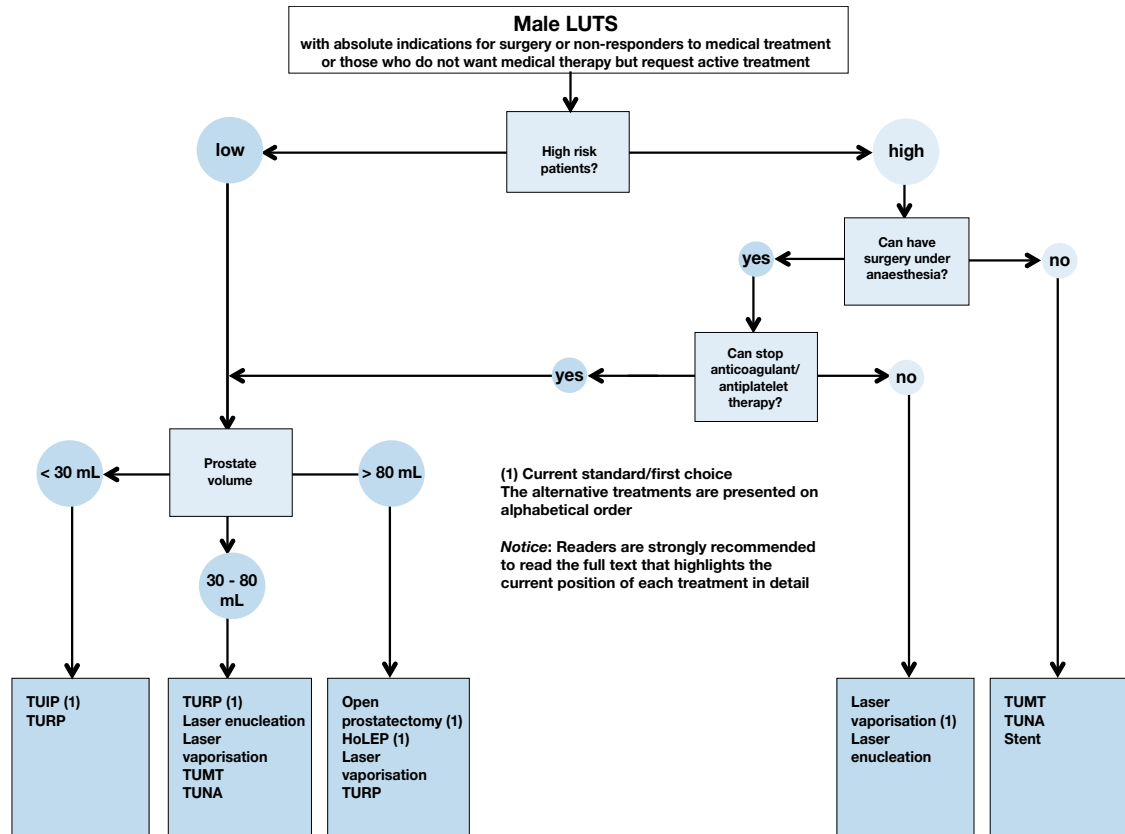

Figure 3: Treatment algorithm of male LUTS using medical and/or conservative treatment options.
Treatment decisions depend on results assessed during initial evaluation. Note that patients'

preferences may result in different treatment decisions.

LUTS = lower urinary tract symptoms; PDE5I = phosphodiesterase type 5 inhibitors.

Figure 4: Treatment algorithm of bothersome LUTS refractory to conservative/medical treatment or in cases of absolute operation indications. The flowchart was stratified by the patient's ability to have anaesthesia, cardiovascular risk, and prostate size.

Laser vaporisation includes GreenLight, thulium, and diode lasers vaporisation;
Laser enucleation includes holmium and thulium laser enucleation.

HoLEP = holmium laser enucleation; TUIP = transurethral incision of the prostate; TUMT = transurethral microwave therapy; TUNA = transurethral needle ablation; TURP = transurethral resection of the prostate.

3D FOLLOW-UP

3D.1 Watchful waiting (behavioural)

Patients who elect to pursue a WW policy should be reviewed at 6 months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits: IPSS, uroflowmetry, and PVR volume.

3D.2 Medical treatment

Patients receiving α_1 -blockers, muscarinic receptor antagonists, PDE5Is or the combination of α_1 -blockers + 5-ARIs or muscarinic receptor antagonists should be reviewed 4-6 weeks after drug initiation to determine the treatment response. If patients gain symptomatic relief in the absence of troublesome adverse events, drug therapy may be continued. Patients should be reviewed at 6 months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following tests are recommended at follow-up visits: IPSS, uroflowmetry, and PVR volume. FVC or bladder diaries should be used to assess response to treatment for predominant storage symptoms or nocturnal polyuria.

Patients receiving 5-ARIs should be reviewed after 12 weeks and 6 months to determine their response and adverse events. The following are recommended at follow-up visits: IPSS, uroflowmetry and PVR volume.

Men taking 5-ARIs should be followed up regularly using serial PSA testing if life expectancy is > 10 years and if a diagnosis of prostate cancer could alter management. A new baseline PSA should be determined

at 6 months, and any confirmed increase in PSA while on 5-ARIs should be evaluated.

In patients receiving desmopressin, serum sodium concentration should be measured at day 3 and 7 as well as after 1 month, and if serum sodium concentration has remained normal, every 3 months subsequently. The following tests are recommended at follow-up visits: serum-sodium concentration and frequency volume chart. The follow-up sequence should be restarted after dose escalation.

3D.3 Surgical treatment

Patients after prostate surgery should be reviewed 4-6 weeks after catheter removal to evaluate treatment response and adverse events. If patients have symptomatic relief and are without adverse events, no further re-assessment is necessary.

The following tests are recommended at follow-up visit after 4 to 6 weeks: IPSS, uroflowmetry and PVR volume.

Recommendation	LE	GR
Follow-up for all conservative, medical, or operative treatment modalities is based on empirical data or theoretical considerations, but not on evidence-based studies.	3-4	C

5. CONFLICT OF INTEREST

All members of the EAU Non-neurogenic Male LUTS Guidelines Panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is publically accessible through the EAU website. These Guidelines were developed with the financial support of the EAU. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

Guidelines on Male Sexual Dysfunction:

Erectile dysfunction and premature ejaculation

K. Hatzimouratidis (Chair), I. Eardley, F. Giuliano,
I. Moncada, A. Salonia

1. INTRODUCTION

1.1 Aim

The aim of these guidelines is to present the current evidence for the diagnosis and treatment of patients suffering from erectile dysfunction (ED) and premature ejaculation (PE). ED and PE are the two main complaints in male sexual medicine [1, 2]. Pharmacological therapies have completely changed the diagnostic and therapeutic approach to ED and the Guidelines Office of the European Association of Urology (EAU) has appointed an Expert Panel to update previously published EAU guidelines for ED or impotence.

1.2 Publication history

The first EAU Guidelines on Erectile Dysfunction were published in 2000 with subsequent updates in 2001, 2002, 2004, 2005, 2009, 2013 and 2014. In particular, the 2009 document presented a significant update of the previous publication with the inclusion of the topic "Premature Ejaculation" and the text was renamed to "EAU Guidelines on Male Sexual Dysfunction" [3]. In 2011 the Panel decided to develop separate guidelines addressing Penile Curvature, which resulted in a separate publication in 2012 [4]. In 2014 a guideline on Priapism was completed [5].

For this 2015 version a literature search was performed to identify the efficacy and safety of avanafil (a new phosphodiesterase type 5 inhibitors) in men with ED, and a section on the topic was included. Additionally, the text has been updated and significantly reduced so that only key information is included and re-formatted according to the EAU template for non-oncology Guidelines, so that all Guidelines follow a similar format.

Alongside several scientific summaries published in the EAU scientific journal, European Urology [6-10], a quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices, presenting the main findings of the Male Sexual Dysfunction guidelines. These are abridged versions which may require consultation together with the full text versions. All available material can be viewed and downloaded for personal use at the EAU website, which also includes a selection of translations produced by national urological associations: <http://www.uroweb.org/guidelines/online-guidelines/>.

This document was peer reviewed prior to publication.

1.3 Panel composition

The EAU Guidelines Panel on Male Sexual Dysfunction consists of urologists. Members of this Panel have been selected based on their expertise to represent the professionals treating patients suffering from ED.

2. METHODS

References used in this text are graded according to their Level of Evidence (LE) and Guidelines are given a Grade of Recommendation (GR). In this 2015 EAU Guidelines compilation, all standard information on LE and GR has been taken out of the individual Guidelines topics for the sake of brevity. The methodology section (see the introduction chapter of the complete book) outlines the LE and GR criteria which are used throughout the Guidelines, according to a classification system modified from the Oxford Centre for Evidence-based Medicine Levels of Evidence.

For both conditions (ED and PE) a systemic literature search was performed by the panel members. The MedLine database was searched using the major Medical Subject Headings (MeSH) terms "erectile dysfunction", "sexual dysfunction" "ejaculation". All articles published between January 2009 (previous update) and October 2014 were considered for review. For Premature Ejaculation the MedLine search was supplemented by the term "premature ejaculation" in all search fields, for the 2015 print, covering a time frame up to October 2014. The Panel also identified critical problems and knowledge gaps, setting priorities for future clinical research.

3. THE GUIDELINE

3A ERECTILE DYSFUNCTION

3A.1 Epidemiology/aetiology/pathophysiology

Erection is a complex phenomenon which implies a delicate and coordinated equilibrium among the neurological, vascular and the tissue compartments. It includes arterial dilation, trabecular smooth muscle relaxation, and activation of the corporeal veno-occlusive mechanism [11]. ED is defined as the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual performance [12]. ED may affect physical and psychosocial health and may have a significant impact on the quality of life (QoL) of sufferers and their partners [13-15]. There is increasing evidence that ED can be an early manifestation of coronary artery and peripheral vascular disease. ED should not be regarded only as a QoL issue, but also as a potential warning sign of cardiovascular disease (CVD) [16-18].

3A.1.1 Epidemiology

Epidemiological data have shown a high prevalence and incidence of ED worldwide. Among others, the Massachusetts Male Aging Study (MMAS) [13] reported an overall prevalence of 52% ED in non-institutionalised men aged 40-70 years in the Boston area; specific prevalence for minimal, moderate, and complete ED was 17.2%, 25.2%, and 9.6%, respectively. In the Cologne study of men aged 30-80 years, the prevalence of ED was 19.2%, with a steep age-related increase from 2.3% to 53.4% [19]. The incidence rate of ED (new cases per 1,000 men annually) was 26 in the long-term data from the MMAS study [20] and 19.2 (mean follow-up of 4.2 years) in a Dutch study [21]. In a cross-sectional real-life study among men seeking first medical help for new-onset ED, one in four patients was younger than 40 years, with almost 50% of the young men complaining of severe ED [22]. Differences between these studies can be explained by differences in methodology, in the ages, and socioeconomic and cultural status of the populations studied.

3A.1.2 Risk factors

ED shares both unmodifiable and modifiable common risk factors with CVD (e.g., obesity, diabetes mellitus, dyslipidemia, metabolic syndrome, lack of exercise, and smoking) [15, 23, 24]. In this context, men with mild ED have similar risk factors to those of a general ED clinical trial population [25]. Thus, mild ED emerged as an important indicator of risk for associated underlying disease (CVDs) [25]. A number of studies have shown some evidence that lifestyle modification [18, 26] and pharmacotherapy [26, 27] for cardiovascular risk factors may be of help in improving sexual function in men with ED. However, it should be emphasised that more controlled prospective studies are necessary to determine the effects of exercise or other lifestyle changes in prevention or treatment of ED [17].

Epidemiological studies have demonstrated consistent evidences for an association between lower urinary tract symptoms (LUTS)/benign prostatic hyperplasia (BPH) and sexual dysfunction regardless of age, and other comorbidities, and various lifestyle factors [28]. The Multinational Survey on the Aging Male (MSAM-7) study – performed in the US, France, Germany, Italy, Netherlands, Spain, and UK - systematically investigated the relationship between LUTS and sexual dysfunction in > 12,000 men aged 50-80 years. Of 83% men self-reported to be sexually-active, the overall prevalence of LUTS was 90%, with an overall prevalence of ED of 49%, and a reported complete absence of erection in 10% of patients. Moreover, the overall prevalence of ejaculation disorders was 46% [29].

3A.1.3 Pathophysiology

The pathophysiology of ED may be vasculogenic, neurogenic, anatomical, hormonal, drug-induced and/or psychogenic (Table 1) [11].

Table 1: Pathophysiology of ED

Vasculogenic	
-	Cardiovascular disease (hypertension, coronary artery disease, peripheral vasculopathy, etc.)
-	Diabetes mellitus
-	Hyperlipidaemia
-	Smoking
-	Major pelvic surgery (RP) or radiotherapy (pelvis or retroperitoneum)
Neurogenic	
<i>Central causes</i>	
-	Degenerative disorders (multiple sclerosis, Parkinson's disease, multiple atrophy, etc.)
-	Spinal cord trauma or diseases
-	Stroke
-	Central nervous system tumours
<i>Peripheral causes</i>	
-	Type 1 and 2 diabetes mellitus
-	Chronic renal failure
-	Polyneuropathy
-	Surgery (major surgery of pelvis/retroperitoneum, RP, colorectal surgery, etc.)
-	Surgery of the urethra (urethral stricture urethroplasty, etc)
Anatomical or structural	
-	Hypospadias, epispadias
-	Micropenis
-	Peyronie's disease
Hormonal	
-	Hypogonadism
-	Hyperprolactinemia
-	Hyper- and hypothyroidism
-	Hyper- and hypocortisolism (Cushing's disease, etc.)
-	Panhypopituitarism and multiple endocrine disorders
Drug-induced	
-	Antihypertensives (thiazide diuretics, etc.)
-	Antidepressants (selective serotonin reuptake inhibitors, tricyclics)
-	Antipsychotics (neuroleptics, etc.)
-	Antiandrogens (GnRH analogues and antagonists)
-	Recreational drugs (alcohol, heroin, cocaine, marijuana, methadone, synthetic drugs, anabolic steroids, etc.)
Psychogenic	
-	Generalised type (e.g., lack of arousability and disorders of sexual intimacy)
-	Situational type (e.g., partner-related, performance-related issues or due to distress)
Trauma	
-	Penile fracture
-	Pelvic fractures

3A.1.4 Post-radical prostatectomy ED, post-radiotherapy ED & post-brachytherapy ED

Radical prostatectomy (RP) in any form (open, laparoscopic, or robotic) is a widely performed procedure for patients with clinically localised prostate cancer (PCa) and a life expectancy of at least 10 years. This procedure may lead to treatment-specific sequelae affecting health-related QoL. This outcome has become increasingly important with the more frequent diagnosis of PCa in younger patients [30, 31]. Research has shown that 25-75% of men experience post-operative ED [32]. Given the growing clinical importance of robot-assisted RP (RARP), this type of surgery is becoming the paradigm for post-operative functional results. A systematic review has shown a significant advantage in favour of RARP in comparison with retropubic RP in terms of 12-month potency rates [33], without significant difference between laparoscopic RP and RARP. However, more controlled prospective studies are necessary to determine the actual superiority of RARP in terms of post-operative ED rates [34]. Overall, patient age and surgical volume, with the consequent ability to preserve neurovascular bundles, seem to be the main factors in promoting the highest rates of post-operative potency [30, 31].

Pre-operative potency is a major factor associated with the recovery of erectile function (EF) after surgery. Patients being considered for nerve-sparing RP (NSRP) should ideally be potent pre-operatively [30, 31]. Overall, the temporal aspects are of major clinical importance in terms of post-operative recovery of EF. Available data confirm that post-operative EF recovery can also occur years following RP (and up to 48 months). Likewise, it is shared opinion that the timing of post-operative therapy (any type) should be as close as possible to the surgical procedure [31,32].

ED is also a common sequela after external beam radiotherapy and brachytherapy for PCa [35, 36]. The mechanisms contributing to ED after prostate irradiation involve injury to the neurovascular bundles, penile vasculature, and cavernosal structural tissue [35, 36]. Alternative treatments for PCa including cryotherapy and high-intensity focused ultrasound (US) are associated with equivalent or worsened rates of ED compared to surgery or radiation therapy [37, 38].

3A.1.5 **Conclusions on the epidemiology/aetiology/pathophysiology of ED**

	LE
ED is common worldwide.	2b
ED shares risk factors with cardiovascular disease.	2b
Lifestyle modification (regular exercise and decrease in body mass index) can improve erectile function.	1b
ED is a symptom, not a disease. Some patients may not be properly evaluated or receive treatment for an underlying disease or condition that may be causing ED.	4
ED is common after RP, irrespective of the surgical technique used.	2b
ED is common after external radiotherapy and brachytherapy.	2b
ED is common after cryotherapy and high-intensity focused US.	2b

3A.2 **Classification**

ED is commonly classified into three categories based on its aetiology. These include organic, psychogenic and mixed ED. However, this classification should be used with caution since most cases are actually of mixed aetiology. It is therefore suggested to use the term primary organic or primary psychogenic.

3A.3 **Diagnostic evaluation**

3A.3.1 **Basic work-up**

The first step in evaluating ED is always a detailed medical and sexual history of patients, and partners when available [39, 40]. In this context, taking a comprehensive medical history may reveal one of the many common disorders associated with ED [39, 40]. It is important to establish a relaxed atmosphere during history-taking. This will make it easier to i) ask questions about EF and other aspects of the sexual history; and, ii) to explain the diagnosis and therapeutic approach to the patient and his partner. Figure 1 gives the minimal diagnostic evaluation (basic work-up) in patients with ED.

3A.3.2 **Sexual history**

The sexual history must include (when available) information about sexual orientation, previous and current sexual relationships, current emotional status, onset and duration of the erectile problem, and previous consultations and treatments. The sexual health status of the partner(s) (when available) can also be useful. A detailed description should be made of the rigidity and duration of both sexually-stimulated and morning erections and of problems with sexual desire, arousal, ejaculation, and orgasm [39, 41]. Validated psychometric questionnaires, such as the International Index for Erectile Function (IIEF) [42] or its short version Sexual Health Inventory for Men (SHIM), help to assess the different sexual function domains (i.e. sexual desire, EF, orgasmic function, intercourse, and overall satisfaction), as well as the impact of a specific treatment modality. Psychometric analysis also supports the use of the erectile hardness score for the assessment of penile rigidity in practice and in clinical trials research [43]. In cases of clinical depression, the use of a 2-question scale for depression is recommended in the everyday clinical practice: "During the past month have you often been bothered by feeling down, depressed or hopeless? During the past month have you often been bothered by little interest or pleasure, doing things?"[44]. Patients should always be screened for symptoms of possible hypogonadism (= testosterone deficiency), including decreased energy, libido, fatigue, and cognitive impairment, as well as for LUTS. For this specific purpose, screening questionnaires, such as the International Prostate Symptom Score may be utilised [45].

3A.3.3 **Physical examination**

Every patient must be given a physical examination focused on the genitourinary, endocrine, vascular, and neurological systems [46, 47]. A physical examination may reveal unsuspected diagnoses, such as Peyronie's disease, pre-malignant or malignant genital lesions, prostatic enlargement or irregularity/nodularity, or signs and symptoms suggesting hypogonadism (small testes, alterations in secondary sexual characteristics etc). Blood pressure and heart rate should be measured if they have not been assessed in the previous 3-6 months.

3A.3.4 **Laboratory testing**

Laboratory testing must be tailored to the patient's complaints and risk factors. Patients may need a fasting blood glucose or HbA1c and lipid profile if not recently assessed. Hormonal tests include an early morning total testosterone. If indicated, bioavailable or calculated-free testosterone may be needed to corroborate total testosterone measurements. However, the threshold of testosterone to maintain ED is low and ED is usually a symptom of more severe cases of hypogonadism [23, 48-50]. For levels > 8 nmol/l the relationship between circulating testosterone and sexual functioning is very low [23, 48-50]. Additional laboratory tests may be considered in selected patients (eg, prostate-specific antigen (PSA) [51]; prolactin, and luteinising hormone [52]). Although physical examination and laboratory evaluation of most men with ED may not reveal the exact diagnosis, these opportunities to identify critical comorbid conditions should not be missed [47].

Figure 1: Minimal diagnostic evaluation (basic work-up) in patients with ED

ED = erectile dysfunction; IIEF = International Index of Erectile Function.

3A.3.5 **Cardiovascular system and sexual activity: the patient at risk**

Patients who seek treatment for sexual dysfunction have a high prevalence of CVDs. Epidemiological surveys have emphasised the association between cardiovascular and metabolic risk factors and sexual dysfunction in both men [53] and women [54]. Overall, ED can improve the sensitivity of screening for asymptomatic CVD in men with diabetes [55, 56]. ED significantly increases the risk of CVD, coronary heart disease, stroke, and all-cause mortality, and the increase is probably independent of conventional cardiovascular risk factors [16, 18, 57].

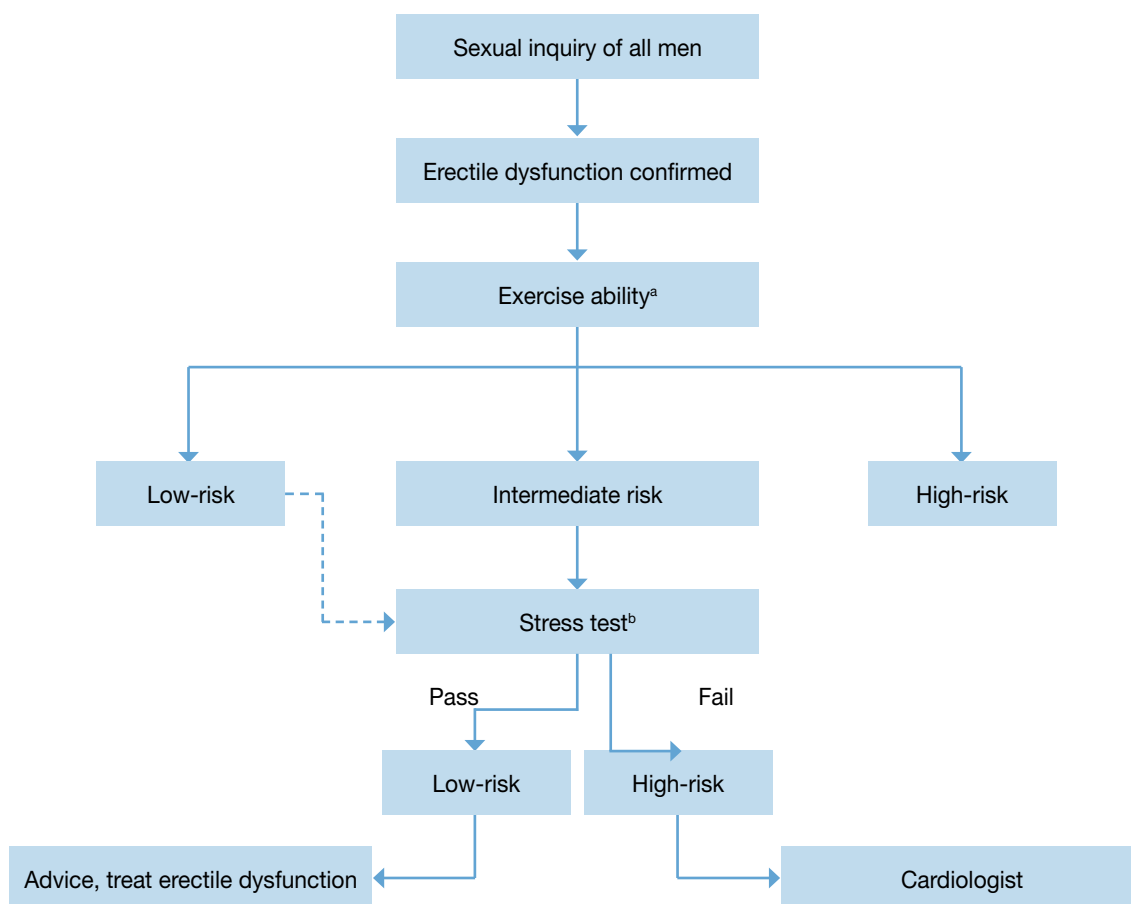

The EAU Guidelines for diagnosing and treating men with ED have been adapted from previously published recommendations from the Princeton Consensus conferences on sexual dysfunction and cardiac risk [16]. The Princeton Consensus (Expert Panel) Conference is dedicated to optimising sexual function and preserving cardiovascular health [58-60]. Accordingly, patients with ED can be stratified into three cardiovascular risk categories (Table 2), which can be used as the basis for a treatment algorithm for initiating or resuming sexual activity (Figure 2). It is also possible for the clinician to estimate the risk of sexual activity in most patients from their level of exercise tolerance, which can be determined when taking the patient's history [27].

Table 2: Cardiac risk stratification (based on 2nd Princeton Consensus [59])

Low-risk category	Intermediate-risk category	High-risk category
Asymptomatic, < 3 risk factors for CAD (excluding sex)	≥ 3 risk factors for CAD (excluding sex)	High-risk arrhythmias
Mild, stable angina (evaluated and/or being treated)	Moderate, stable angina	Unstable or refractory angina
Uncomplicated previous MI	Recent MI (> 2, < 6 weeks)	Recent MI (< 2 weeks)
LVD/CHF (NYHA class I)	LVD/CHF (NYHA class II)	LVD/CHF (NYHA class III/IV)
Post-successful coronary Revascularisation	Non-cardiac sequelae of atherosclerotic disease (e.g., stroke, peripheral vascular disease)	Hypertrophic obstructive and other cardiomyopathies
Controlled hypertension		Uncontrolled hypertension
Mild valvular disease		Moderate-to-severe valvular disease

CAD = coronary artery disease; CHF = congestive heart failure; LVD = left ventricular dysfunction; MI = myocardial infarction; NYHA = New York Heart Association.

Figure 2: Treatment algorithm for determining level of sexual activity according to cardiac risk in ED (based on 3rd Princeton Consensus) [60]

^a Sexual activity is equivalent to walking 1 mile on the flat in 20 min or briskly climbing two flights of stairs in 10 s.

^b Sexual activity is equivalent to 4 min of the Bruce treadmill protocol.

3A.3.5.1 *Low-risk category*

The low-risk category includes patients who do not have any significant cardiac risk associated with sexual activity. Low-risk is typically implied by the ability to perform exercise of modest intensity, which is defined as ≥ 6 "metabolic equivalents of energy expenditure in the resting state" without symptoms. According to current knowledge of the exercise demand or emotional stress associated with sexual activity, low-risk patients do not need cardiac testing or evaluation before the initiation or resumption of sexual activity or therapy for sexual dysfunction.

3A.3.5.2 *Intermediate- or indeterminate-risk category*

The intermediate- or indeterminate-risk category consists of patients with an uncertain cardiac condition or patients whose risk profile requires testing or evaluation before the resumption of sexual activity. Based upon the results of testing, these patients may be moved to either the high- or low-risk group. A cardiology consultation may be needed in some patients to help the primary physician determine the safety of sexual activity.

3A.3.5.3 *High-risk category*

High-risk patients have a cardiac condition that is sufficiently severe and/or unstable for sexual activity to carry a significant risk. Most high-risk patients have moderate-to-severe symptomatic heart disease. High-risk individuals should be referred for cardiac assessment and treatment. Sexual activity should be stopped until the patient's cardiac condition has been stabilised by treatment, or a decision made by the cardiologist and/or internist that it is safe to resume sexual activity.

3A.3.6 ***Specialised diagnostic tests***

Most patients with ED can be managed within the sexual care setting; conversely, some patients may need specific diagnostic tests (Tables 3 and 4).

3A.3.6.1 *Nocturnal penile tumescence and rigidity test*

The nocturnal penile tumescence and rigidity assessment should be done on at least two nights. A functional erectile mechanism is indicated by an erectile event of at least 60% rigidity recorded on the tip of the penis that lasts for ≥ 10 min [61].

3A.3.6.2 *Intracavernous injection test*

The intracavernous injection test gives limited information about vascular status. A positive test is a rigid erectile response (unable to bend the penis) that appears within 10 min after the intracavernous injection and lasts for 30 min [62]. Overall, the test is inconclusive as a diagnostic procedure and a duplex Doppler study of the penis should be requested, if clinically warranted.

3A.3.6.3 *Duplex ultrasound of the penis*

A peak systolic blood flow > 30 cm/s, an end-diastolic velocity of < 3 cm/s and a resistance index > 0.8 are generally considered normal [63]. Further vascular investigation is unnecessary when a Duplex examination is normal.

3A.3.6.4 *Arteriography and dynamic infusion cavernosometry or cavernosography*

Arteriography and dynamic infusion cavernosometry or cavernosography should be performed only in patients who are being considered for vascular reconstructive surgery [64].

3A.3.6.5 *Psychiatric assessment*

Whenever clinically indicated, patients with psychiatric disorders should be referred to a psychiatrist who is particularly interested in sexual health. In younger patients (< 40 years) with long-term primary ED [22], psychiatric assessment may be helpful before any organic assessment is carried out.

3A.3.6.6 *Penile abnormalities*

Surgical correction may be needed for patients with ED due to penile abnormalities (e.g. hypospadias, congenital curvature, or Peyronie's disease with preserved rigidity).

3A.3.7 ***Patient education - consultation and referrals***

Consultation with the patient should include a discussion of the expectations and needs of both the patient and his stable sexual partner, if available. It should also review both the patient's and partner's understanding of ED and the results of diagnostic tests, and provide a rational selection of treatment options [65]. Patient and partner education is an essential part of ED management [65, 66].

Table 3: Indications for specific diagnostic tests

Primary ED (not caused by organic disease or psychogenic disorder).
Young patients with a history of pelvic or perineal trauma, who could benefit from potentially curative vascular surgery.
Patients with penile deformities which might require surgical correction (e.g., Peyronie's disease, congenital curvature).
Patients with complex psychiatric or psychosexual disorders.
Patients with complex endocrine disorders.
Specific tests may be indicated at the request of the patient or his partner.
Medico-legal reasons (e.g., implantation of penile prosthesis, sexual abuse).

Table 4: Specific diagnostic tests

NTPR using Rigiscan
Vascular studies
- Intracavernous vasoactive drug injection
- Penile Dynamic Duplex Doppler study
- Penile Dynamic Infusion Cavernosometry and Cavernosography
- Internal pudendal arteriography
Neurological studies (e.g., bulbocavernosus reflex latency, nerve conduction studies)
Endocrinological studies
Specialised psychodiagnostic evaluation

3A.3.8 Recommendations for the diagnostic evaluation of ED

	LE	GR
A comprehensive medical and sexual history is needed.	3	B
Clinical use of validated questionnaire related to ED may help to assess all sexual function domains and the effect of a specific treatment modality.	3	B
Physical examination is needed in the initial assessment of men with ED to identify underlying medical conditions that may be associated with ED.	4	B
Routine laboratory tests, including glucose-lipid profile and total testosterone, are required to identify and treat any reversible risk factors and lifestyle factors that can be modified.	4	B
Specific diagnostic tests are indicated by only a few conditions.	4	B

ED = erectile dysfunction.

3A.4. Disease management**3A.4.1 Treatment options**

ED may be associated with modifiable or reversible risk factors, including lifestyle or drug-related factors. These factors may be modified either before, or at the same time as, specific therapies are used. Likewise, ED may be associated with concomitant and underlying conditions (such as, for instance, endocrine disorders and metabolic disorders - e.g. diabetes - some cardiovascular problems - e.g. hypertension) which should always be well-controlled as the first step of ED treatment. As a rule, ED can be treated successfully with current treatment options, but cannot be cured. The only exceptions are psychogenic ED, post-traumatic arteriogenic ED in young patients, and hormonal causes (e.g. hypogonadism and hyperprolactinaemia [49, 52]), which potentially can be cured with specific treatment. Most men with ED will be treated with therapeutic options that are not cause specific. This results in a structured treatment strategy that depends on efficacy, safety, invasiveness and cost, as well as patient preference [65]. In this context, physician-patient (partner) dialogue is essential throughout the management of ED. The assessment of treatment options must be tailored according to patient and partner satisfaction, QoL factors as well as treatment-related safety and efficacy. A treatment algorithm for ED is shown in Figure 3.

3A.4.2 Lifestyle management in ED with concomitant risk factors

The basic work-up of the patient must identify reversible risk factors for ED. Lifestyle changes and risk factor modification must precede or accompany any pharmacological treatment. Major clinical potential benefits of lifestyle changes may be obtained in men with specific comorbid cardiovascular or metabolic disorders, such as diabetes or hypertension [17, 67].

3A.4.3 **Erectile dysfunction after radical prostatectomy**

Use of pro-erectile drugs following RP is important in achieving post-operative EF. Several trials have shown higher rates of EF recovery after RP in patients receiving any drug (therapeutic or prophylactic) for ED. Early compared with delayed EF treatment seems to impact on the natural healing time of potency [31]. Currently available therapeutic armamentarium follows the treatment algorithm for ED which is shown in Figure 3.

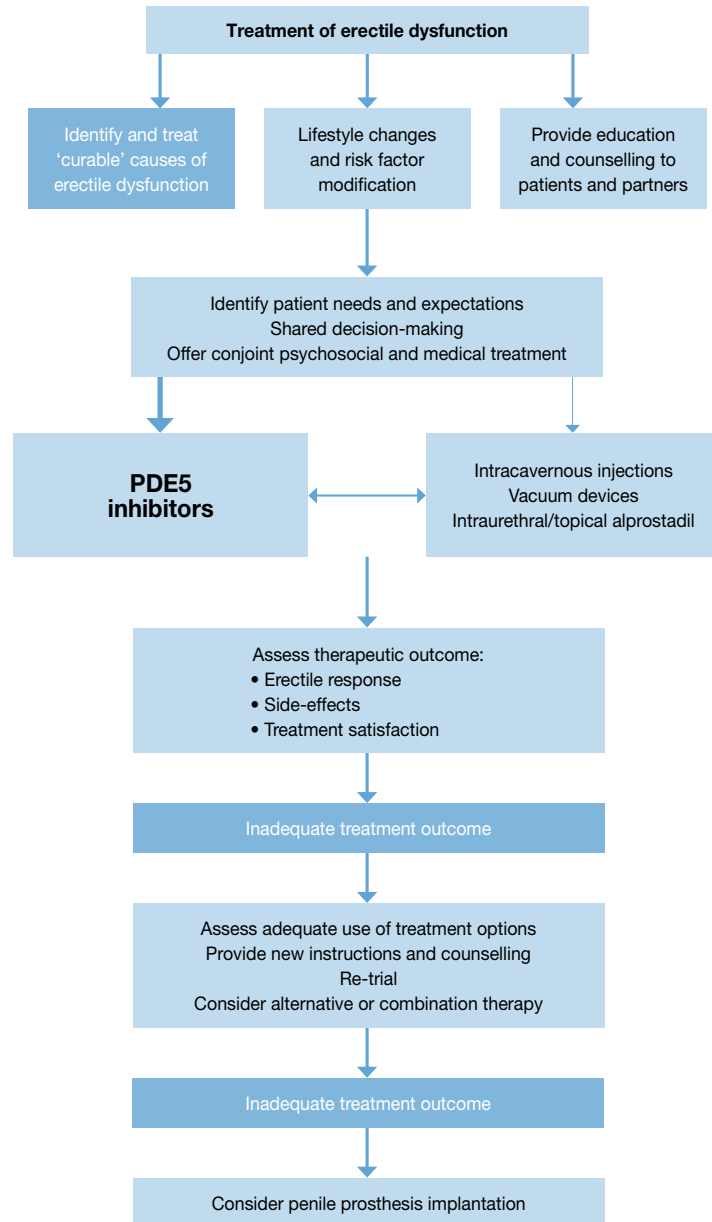

The management of post-RP ED has been revolutionised by the advent of phosphodiesterase 5 inhibitors (PDE5Is), with their demonstrated efficacy, ease of use, good tolerability, excellent safety, and positive impact on QoL. It must be emphasised that post-RP ED patients are poor responders to PDE5Is. However, PDE5Is are the first-line therapy in patients who have undergone nerve-sparing (NS) surgery regardless of the surgical technique used [30, 31]. A number of clinical parameters have been identified as potential predictors of PDE5Is in men undergoing RP. Patient age and quality of NS technique are a key factors in preserving post-operative EF [30, 31, 33]. The response rate to sildenafil treatment for ED after RP in different trials has ranged from 35% to 75% among those who underwent NSRP and from 0% to 15% among those who underwent non-NSRP [31, 68]. Early use of high-dose sildenafil after RP has been suggested to be associated with preservation of smooth muscle within the corpora cavernosa [69]. Daily sildenafil also results in a greater return of spontaneous normal EF after RP compared to placebo following bilateral NSRP in patients who were fully potent before surgery [70].

Effectiveness of tadalafil and vardenafil as on-demand treatment has been evaluated in post-RP ED. A large multicentre trial in Europe and the USA has studied tadalafil in patients with ED following bilateral NS surgery. Erectile function was improved in 71% of patients treated with 20 mg tadalafil vs. 24% of those treated with placebo, while the rate of successful intercourse attempts was 52% with 20 mg tadalafil vs. 26% with placebo [31, 71]. Similarly, vardenafil has been tested in patients with ED following NSRP in a randomised, multicentre, prospective, placebo-controlled study in North America [31, 72]. Following bilateral NSRP, EF improved by 71% and 60% with 10 and 20 mg vardenafil, respectively. An extended analysis of the same cohort of patients showed the benefit of vardenafil compared to placebo in terms of intercourse satisfaction, hardness of erection, orgasmic function, and overall satisfaction with sexual experience [31, 73]. Moreover, a randomised, double-blind, double-dummy trial in men \leq 68 yr of age and normal pre-operative EF who underwent NSRP at 50 centres from nine European countries and Canada, compared tadalafil once daily with placebo [74]. Tadalafil was most effective on drug-assisted EF in men with ED following NSRP, and data suggested a potential role for tadalafil once daily - provided early after surgery - in contributing to the recovery of post-operative EF and possibly protecting from penile structural changes [74]. Unassisted EF was not improved after cessation of active therapy for 9 months [74]. Moreover, data suggested that the use of tadalafil once daily can significantly shorten the time to EF-recovery post-NSRP compared to placebo [75].

A randomised, double-blind, double-dummy, multicentre, parallel-group study in 87 centres across Europe, Canada, South Africa and the USA, compared on-demand and nightly dosing of vardenafil in men with ED following bilateral NSRP. In patients whose pre-operative IIEF EF domain score was \geq 26, vardenafil was efficacious when used on demand, supporting a paradigm shift towards on-demand dosing with PDE5Is in post-RP ED [76]. A double-blind, placebo-controlled, parallel-group, study in 298 patients with ED after bilateral NSRP randomised to 100 or 200 mg avanafil or placebo (taken 30 minutes before sexual activity) for 12 weeks showed significantly greater increases in SEP2 (sexual encounter profile) and SEP3 and change in mean IIEF-EF domain score with 100 and 200 mg avanafil vs. placebo ($p < 0.01$) [77]. Following dosing with avanafil 36.4% (28 of 77) of sexual attempts (SEP3) at 15 minutes or less were successful vs. 4.5% (2 of 44) for placebo ($p < 0.01$) [77].

Historically, the treatment options for post-operative ED have included intracavernous injections [31, 78], urethral microsuppository [31, 79], vacuum device therapy [31, 80], and penile implants [31, 81, 82]. Intracavernous injections and penile implants are still suggested as second- and third-line treatments, respectively, when oral PDE5Is are not adequately effective or contraindicated for post-operative patients (Sections 3A.4.6 and 3A.4.7).

Figure 3: Treatment algorithm for erectile dysfunction

3A.4.4 **Causes of ED that can be potentially treated with a curative intent**

3A.4.4.1 *Hormonal causes*

The advice of an endocrinologist may be beneficial for managing patients with hormonal abnormalities [52]. Testosterone deficiency is either a result of primary testicular failure or secondary to pituitary/hypothalamic causes (e.g. a functional pituitary tumour resulting in hyperprolactinaemia) [52, 83]. When clinically indicated [25], testosterone supplementation (TS) (intramuscular, oral, or transdermal) is effective, but should only be used after other endocrinological causes for testicular failure have been excluded [23, 49, 84]. Before initiating TS, digital rectal examination, serum PSA test, haematocrit, liver function tests and lipid profile should be performed [23, 49]. Patients who are given TS should be monitored for clinical response, elevation of the haematocrit and development of hepatic or prostatic disorders [23, 49]. TS is controversial in men with a history of PCa (LE: 4) [85]. Since there is limited evidence suggesting that TS may not pose an undue risk of PCa recurrence or progression, TS is contraindicated in patients with untreated PCa (LE: 4).

TS is contraindicated in patients with unstable cardiac disease. Conversely, the role of testosterone in the cardiovascular health of men is controversial. Clinical trials examining TS have been insufficiently powered to provide definitive and unequivocal evidence of adverse events in terms of cardiovascular outcomes [86-91]. As a matter of fact, current guidelines from the Endocrine Society make no recommendations on whether patients with heart disease should be screened for hypogonadism and do not recommend supplementing patients

with heart disease to improve survival [48]. However, a recent comprehensive systematic review and meta-analysis of all placebo-controlled randomised clinical trials (RCTs) on the effect of TS on cardiovascular-related problems did not support a causal role between TS and adverse cardiovascular events [92].

3A.4.4.2 *Post-traumatic arteriogenic ED in young patients*

In young patients with pelvic or perineal trauma, surgical penile revascularisation has a 60-70% long-term success rate [93]. The lesion must be confirmed by penile pharmaco-arteriography. Corporeal veno-occlusive dysfunction is a contraindication to revascularisation and must be excluded by dynamic infusion cavernosometry or cavernosography. Vascular surgery for veno-occlusive dysfunction is no longer recommended because of poor long-term results [93].

3A.4.4.3 *Psychosexual counselling and therapy*

For patients with a significant psychological problem, psychosexual therapy may be given either alone or with another therapeutic approach. Psychosexual therapy requires ongoing follow-up and has had variable results [94].

3A.4.5 **First-line therapy**

3A.4.5.1 *Oral pharmacotherapy*

PDE5 hydrolyses cGMP in the cavernosal tissue. Inhibition of PDE5 results in smooth muscle relaxation with increased arterial blood flow, leading to compression of the subtunical venous plexus and penile erection [95]. Four potent selective PDE5Is have been approved by the European Medicines Agency (EMA) for the treatment of ED [96]. They are not initiators of erection and require sexual stimulation to facilitate an erection. Efficacy is defined as an erection with rigidity sufficient for vaginal penetration.

3A.4.5.1.1 Sildenafil

Sildenafil was launched in 1998 and was the first PDE5I available on the market [97]. It is administered in doses of 25, 50 and 100 mg. The recommended starting dose is 50 mg and should be adapted according to the patient's response and side-effects. Sildenafil is effective from 30-60 min after administration. Its efficacy is reduced after a heavy, fatty meal due to prolonged absorption. Efficacy may be maintained for up to 12 h [98]. The pharmacokinetic data of sildenafil are presented in Table 5. Adverse events (Table 6) are generally mild in nature and self-limited by continuous use [99, 100]. After 24 weeks in a dose-response study, improved erections were reported by 56%, 77% and 84% of a general ED population taking 25, 50 and 100 mg sildenafil, respectively, compared to 25% of men taking placebo [97]. Sildenafil significantly improved patient scores for IIEF, SEP2, SEP3, and General Assessment Questionnaire (GAQ) and treatment satisfaction. The efficacy of sildenafil in almost every subgroup of patients with ED has been successfully established. The overall level of evidence and grade of recommendation is Level 1 Grade A. Recently, an orally disintegrating tablet (ODT) of sildenafil citrate at the dosage of 50 mg has been developed mainly for the benefit of patients who have difficulty swallowing solid dosage forms.

3A.4.5.1.2 Tadalafil

Tadalafil was licenced for treatment of ED in February 2003 and is effective from 30 min after administration, with peak efficacy after about 2 h. Efficacy is maintained for up to 36 h [101] and is not affected by food. It is administered in on-demand doses of 10 and 20mg and also an alternative daily dose of 5mg. The recommended on-demand starting dose is 10 mg and should be adapted according to the patient's response and side-effects. Pharmacokinetic data of tadalafil are presented in Table 5. Adverse events (Table 6) are generally mild in nature and self-limited by continuous use. In premarketing studies, after 12 weeks of treatment and in a dose-response study, improved erections were reported by 67% and 81% of a general ED population taking 10 and 20 mg tadalafil, respectively, compared to 35% of men in the control placebo group [101]. Tadalafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction. Efficacy has been confirmed in post-marketing studies. The efficacy of tadalafil in almost every subgroup of patients with ED, thus including difficult-to-treat subgroups (e.g. diabetes mellitus), has been successfully established. The overall level of evidence and grade of recommendation is Level 1 Grade A [102].

3A.4.5.1.3 Vardenafil

Vardenafil became commercially available in March 2003 and is effective from 30 min after administration [102]. Its effect is reduced by a heavy, fatty meal (> 57% fat). Five, 10 and 20 mg doses have been approved for on-demand treatment of ED. The recommended starting dose is 10 mg and should be adapted according to the patient's response and side-effects [103]. Pharmacokinetic data of vardenafil are presented in Table 5. Adverse events (Table 6) are generally mild in nature and self-limited by continuous use [103]. After 12 weeks in a dose-response study, improved erections were reported by 66%, 76% and 80% of a

general ED population taking 5, 10 and 20 mg vardenafil, respectively, compared with 30% of men taking placebo [103, 104]. Vardenafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction. Efficacy has been confirmed in post-marketing studies [103, 104]. The efficacy of vardenafil in almost every subgroup of patients with ED, thus including difficult-to-treat subgroups (e.g. diabetes mellitus), has been successfully established. The overall level of evidence and grade of recommendation is Level 1 Grade A. More recently, an ODT of vardenafil has been released [104]. Orodispersable tablet formulations offer improved convenience over film-coated formulations and may be preferred by patients. Absorption is unrelated to food intake and they exhibit better bioavailability compared to film-coated tablets [105]. The efficacy of vardenafil ODT has been demonstrated in several randomised controlled trials and did not seem to differ from the regular formulation [105, 106].

3A.4.5.1.4 Avanafil

Avanafil is a highly-selective PDE5I that recently became commercially available (EMA authorisation June 2013) [107]. Avanafil has a high ratio of inhibiting PDE5 as compared with other PDE subtypes allowing for the drug to be used for ED while minimising adverse effects [108]. Fifty, 100, and 200 mg doses have been approved for on-demand treatment of ED [107]. The recommended starting dose is 100 mg taken orally as needed approximately 30 min before sexual activity and should be adapted according to efficacy and tolerability [107, 109]. In the general population with ED, the mean percentage of attempts resulting in successful intercourse was approximately 47%, 58%, and 59% for the 50 mg, 100 mg, and 200 mg avanafil groups, respectively, as compared with approximately 28% for placebo [107, 109]. Data from sexual attempts made within 15 minutes of dosing showed successful attempts in 64%, 67%, and 71% cases, with avanafil 50, 100, and 200 mg, respectively. The maximum recommended dosing frequency is once per day. Dosage adjustments are not warranted based on renal function, hepatic function, age or gender [109]. Pharmacokinetic data of avanafil are presented in Table 5 [107, 109]. Adverse events (Table 6) are generally mild in nature [107, 109]. Pairwise meta-analytic data from available studies suggested that avanafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ, with an evident dose-response relationship [106, 107]. Administration with food may delay the onset of effect compared with administration in the fasted state but avanafil can be taken with or without food. The efficacy of avanafil in many subgroup of patients with ED, including difficult-to-treat subgroups (e.g diabetes mellitus), has been successfully established. The overall level of evidence and grade of recommendation is Level 1 Grade A.

3A.4.5.1.5 Choice or preference between the different PDE5 inhibitors

To date, no data are available from double- or triple-blind multicentre studies comparing the efficacy and/or patient preference for sildenafil, tadalafil, vardenafil, and avanafil. Choice of drug will depend on the frequency of intercourse (occasional use or regular therapy, 3-4 times weekly) and the patient's personal experience. Patients need to know whether a drug is short- or long-acting, its possible disadvantages, and how to use it.

3A.4.5.1.6 Continuous use of PDE5 inhibitors

Animal studies have shown that chronic use of PDE5Is improves or prevents significantly the intracavernous structure alterations due to age, diabetes, or surgical damage [110-114]. No data exist for a human population. In humans, it has been clinically demonstrated that tadalafil 5 mg once daily in men complaining of ED of various severities was well tolerated and effective [115]. In 2007, tadalafil 2.5 and 5 mg have been approved by the EMA for daily treatment of ED. According to EMA, a once daily regimen with tadalafil 2.5 mg or 5 mg might be considered suitable, based on patient choice and the physician's judgement. In these patients, the recommended dose is 5 mg taken once a day at approximately the same time of day. Overall, tadalafil, 5 mg once daily, provides an alternative to on-demand dosing of tadalafil for couples who prefer spontaneous rather than scheduled sexual activities or who anticipate frequent sexual activity, with the advantage that dosing and sexual activity no longer need to be temporally linked. The appropriateness of the continuous use of a daily regimen should be reassessed periodically [115, 116]. Continuous dosing may also be used in the comorbid patient with LUTS and ED.

Table 5: Summary of the key pharmacokinetic data for the four PDE5 inhibitors currently EMA-approved to treat ED*

Parameter	Sildenafil, 100 mg	Tadalafil, 20 mg	Vardenafil, 20 mg	Avanafil 200mg
C_{max}	560 µg/L	378 µg/L	18.7 µg/L	5.2 µg/L
T_{max} (median)	0.8-1 h	2 h	0.9 h	0.5-0.75 h
$T_{1/2}$	2.6-3.7 h	17.5 h	3.9 h	6 – 17 h
AUC	1685 µg.h/L	8066 µg.h/L	56.8 µg.h/L	11.6 µg.h/L
Protein binding	96%	94%	94%	99%
Bioavailability	41%	NA	15%	8-10%

C_{max} : maximal concentration, T_{max} : time-to-maximum plasma concentration; $T_{1/2}$: plasma elimination half-time; AUC: area under curve or serum concentration time curve.

* Fasted state, higher recommended dose. Data adapted from EMA statements on product characteristics.

Table 6: Common adverse events of the four PDE5 inhibitors currently EMA-approved to treat ED*

Adverse event	Sildenafil	Tadalafil	Vardenafil	Avanafil 200mg
Headache	12.8%	14.5%	16%	9.3%
Flushing	10.4%	4.1%	12%	3.7%
Dyspepsia	4.6%	12.3%	4%	uncommon
Nasal congestion	1.1%	4.3%	10%	1.9%
Dizziness	1.2%	2.3%	2%	0.6%
Abnormal vision	1.9%		< 2%	none
Back pain		6.5%		< 2%
Myalgia		5.7%		< 2%

* Adapted from EMA statements on product characteristics.

3A.4.5.1.7 Safety issues for PDE5 inhibitors

3A.4.5.1.7.1 Cardiovascular safety

Clinical trial results of the four PDE5Is and post-marketing data of sildenafil, tadalafil, and vardenafil have demonstrated no increase in myocardial infarction rates in patients receiving PDE5Is, as part of either RCTs or open-label studies, or compared to expected rates in age-matched male populations. None of the PDE5Is had an adverse effect on total exercise time or time-to-ischæmia during exercise testing in men with stable angina. Chronic or on-demand use is well tolerated with a similar safety profile. All PDE5Is are contraindicated in: i) patients who have suffered from a myocardial infarction, stroke, or life-threatening arrhythmia within the last 6 months; ii) patients with resting hypotension (blood pressure < 90/50 mmHg) or hypertension (blood pressure > 170/100 mmHg); iii) patients with unstable angina, angina with sexual intercourse, or congestive heart failure categorised as New York Heart Association Class 2 or greater.

3A.4.5.1.7.2 Nitrates are contraindicated with PDE5 inhibitors

Absolute contraindication to PDE5Is is represented by patients who are using any form of organic nitrate (e.g. nitroglycerine, isosorbide mononitrate, and isosorbide dinitrate) or nitric oxide (NO) donors (e.g. other nitrate preparations used to treat angina, as well as amyl nitrite or amyl nitrate ("poppers" used for recreation). They result in cGMP accumulation and unpredictable falls in blood pressure and symptoms of hypotension. The duration of interaction between organic nitrates and PDE5Is depends upon the PDE5I and nitrate used. If a PDE5I is taken and the patient develops chest pain, nitroglycerine must be withheld for at least 24 h if sildenafil (and probably also vardenafil) is used (half-life, 4 h), or at least 48 h if tadalafil is used (half-life, 17.5 h), and for no less than 12 h if avanafil is used (half-life, 6-17 h) [117].

3A.4.5.1.7.3 Antihypertensive drugs

Co-administration of PDE5Is with antihypertensive agents (angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, calcium blockers, β -blockers, and diuretics) may result in small additive decreases in blood pressure, which are usually minor. In general, the adverse event profile of a PDE5I is not made worse by a background of antihypertensive medication, even when the patient is taking several antihypertensive agents.

3A.4.5.1.7.4 α -Blocker interactions

All PDE5Is show some interaction with α -blockers, which under some conditions may result in orthostatic hypotension.

- Sildenafil labelling advises that 50 or 100 mg sildenafil should be used with caution in patients taking an α -blocker (especially doxazosin). Hypotension is more likely to occur within 4 h following treatment with an α -blocker. A starting dose of 25 mg is recommended [99].
- Concomitant treatment with vardenafil should only be initiated if the patient has been stabilised on his α -blocker therapy. Co-administration of vardenafil with tamsulosin is not associated with clinically significant hypotension [102-104].
- Tadalafil is not recommended in patients taking doxazosin, but this is not the case for tamsulosin [101, 118].
- Avanafil labelling currently reports that patients should be stable on α -blocker therapy prior to initiating avanafil. In these patients, avanafil should be initiated at the lowest dose of 50 mg. Conversely, in those patients already taking an optimised dose of avanafil, α -blocker therapy should be initiated at the lowest dose.

3A.4.5.1.7.5 Dosage adjustment

Drugs that inhibit the CYP3A4 pathway will inhibit the metabolic breakdown of PDE5Is, thus increasing PDE5Is blood levels (among them, ketoconazole, ritonavir, atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, nelfinavir, saquinavir and telithromycin). Therefore, lower doses of PDE5Is are necessary. However, other agents, such as rifampin, phenobarbital, phenytoin and carbamazepine, may induce CYP3A4 and enhance the breakdown of PDE5Is, so that higher doses of PDE5Is are required. Severe kidney or hepatic dysfunction may require dose adjustments or warnings.

3A.4.5.1.8 Management of non-responders to PDE5 inhibitors

The two main reasons why patients fail to respond to a PDE5I are either incorrect drug use or lack of efficacy of the drug. Data suggest that an adequate trial involves at least six attempts with a particular drug [119]. The management of non-responders depends upon identifying the underlying cause.

3A.4.5.1.8.1 Check that the patient has been using a licensed medication

There is a large black market in PDE5Is. The amount of active drug in these medications varies enormously and it is important to check how and from which source the patient has obtained his medication.

3A.4.5.1.8.2 Check that the medication has been properly prescribed and correctly used

The main reason why patients fail to use their medication correctly is inadequate counselling from their physician. The main ways in which a drug may be incorrectly used are: i) failure to use adequate sexual stimulation; ii) failure to use an adequate dose; and, iii) failure to wait an adequate amount of time between taking the medication and attempting sexual intercourse.

Lack of adequate sexual stimulation: PDE5I action is dependent on the release of NO by the parasympathetic nerve endings in the erectile tissue of the penis. The usual stimulus for NO release is sexual stimulation, and without adequate sexual stimulation (and NO release), the drugs cannot work. Oral PDE5Is take different times to reach maximal plasma concentrations [98, 100, 105, 106, 120-122]. Although pharmacological activity is achieved at plasma levels well below the maximal plasma concentration, there will be a period of time following oral ingestion of the medication during which the drug is ineffective. Even though all four drugs have an onset of action in some patients within 15-30 min of oral ingestion [100, 105, 106, 120-122], most patients require a longer delay between taking the medication [103, 106, 123, 124]. Absorption of sildenafil can be delayed by a meal, and absorption of vardenafil can be delayed by a fatty meal [125]. Absorption of tadalafil is less affected provided there is enough delay between oral ingestion and an attempt at sexual intercourse [120]. When avanafil is taken with a high fat meal, the rate of absorption is reduced with a mean delay in T_{max} of 1.25 h and a mean reduction in C_{max} of 39% (200 mg). There is no effect on the extent of exposure (AUC). The small changes in avanafil C_{max} are considered to be of minimal clinical significance [106-108].

It is possible to wait too long after taking medication before attempting sexual intercourse. The half-life of sildenafil and vardenafil is about 4 h, suggesting that the normal window of efficacy is 6-8 h following drug ingestion, although responses following this time period are well recognised. The half-life of avanafil is 6-17 h. Tadalafil has a longer half-life of ~17.5 h, so the window of efficacy is much longer at ~36 h. Data from uncontrolled studies suggest patient education can help salvage an apparent non-responder to a PDE5I. After emphasising the importance of dose, timing, and sexual stimulation to the patient, EF can be effectively restored following re-administration of the relevant PDE5I [126-128].

3A.4.5.1.8.3 Possible manoeuvres in patients correctly using a PDE5 inhibitor

There is controversial and not-univocal evidence suggesting that, in patients with testosterone deficiency, TS

might improve response to a PDE5I [49, 129-131]. Modification of other risk factors may also be beneficial as discussed in section 3A.4.2. Few data suggest that some patients might respond better to one PDE5I than to another [132]. Although these differences might be explained by variation in drug pharmacokinetics, they do raise the possibility that, despite an identical mode of action, switching to a different PDE5I might be helpful. Moreover, mainly in patients with severe ED, it has been suggested to combine tadalafil daily dosing with short acting PDEI (such as sildenafil), without any significant increase in terms of side-effects [133]. If drug treatment fails, then patients should be offered an alternative therapy such as intracavernosal injection therapy or use of a vacuum erection device (VED).

3A.4.5.2 *Vacuum erection devices*

VEDs provide passive engorgement of the corpora cavernosa, together with a constrictor ring placed at the base of the penis to retain blood within the corpora. Published data report that efficacy, in terms of erections satisfactory for intercourse, is as high as 90%, regardless of the cause of ED and satisfaction rates range between 27% and 94% [134, 135]. Most men who discontinue use of VEDs do so within 3 months. Long-term use of VEDs decreases to 50-64% after 2 years [136]. The commonest adverse events include pain, inability to ejaculate, petechiae, bruising, and numbness, which occur in < 30% of patients [135]. Serious adverse events (skin necrosis) can be avoided if patients remove the constriction ring within 30 min. VEDs are contraindicated in patients with bleeding disorders or on anticoagulant therapy. VEDs may be the treatment of choice in well-informed older patients with infrequent sexual intercourse and comorbidity requiring non-invasive, drug-free management of ED [134, 135].

3A.4.5.3 *Shockwave therapy*

Recently, the use of low-intensity extracorporeal shock wave therapy (LI-SWT) was proposed as a novel treatment for ED [137]. In the first randomised, double-blind, sham-controlled study, it was demonstrated that LI-SWT had a positive short-term clinical and physiological effect on the EF of men who respond to PDE5Is [138]. Moreover, there are preliminary data showing improvement in penile haemodynamics and endothelial function, as well as IIEF-EF domain score in severe ED patients who are poor responders to PDE5Is [139, 140]. Current data are still limited and clear recommendations cannot be given.

3A.4.6 **Second-line therapy**

Patients not responding to oral drugs may be offered intracavernous injections. Success rate is high (85%) [141, 142]. Intracavernous administration of vasoactive drugs was the first medical treatment for ED more than 20 years ago [143, 144].

3A.4.6.1 *Intracavernous injections*

3A.4.6.1.1 *Alprostadil*

Alprostadil (CaverjectTM, Edex/ViridalTM) was the first and only drug approved for intracavernous treatment of ED [143, 144]. Intracavernous alprostadil is most efficacious as monotherapy at a dose of 5-40 µg (of note, 40 µg dose is not registered in every European country). The erection appears after 5-15 min and lasts according to the dose injected. An office-training programme is required for the patient to learn the correct injection process. In cases of limited manual dexterity, the technique may be taught to their partners. The use of an automatic special pen that avoids a view of the needle can resolve fear of penile puncture and simplifies the technique. Efficacy rates for intracavernous alprostadil of >70% have been found in general ED populations, as well as in patient subgroups (e.g. diabetes or CVD), with reported sexual activity after 94% of the injections and satisfaction rates of 87-93.5% in patients and 86-90.3% in partners [143, 144]. Complications of intracavernous alprostadil include penile pain (50% of patients reported pain but pain reported only after 11% of total injections), prolonged erections (5%), priapism (1%), and fibrosis (2%) [143-145]. Pain is usually self-limited after prolonged use. It can be alleviated with the addition of sodium bicarbonate or local anaesthesia [143, 144, 146]. Cavernosal fibrosis (from a small hematoma) usually clears within a few months after temporary discontinuation of the injection program. However, tunical fibrosis suggests early onset of Peyronie's disease and may indicate stopping intracavernosal injections indefinitely. Systemic side-effects are uncommon. The most common is mild hypotension, especially when using higher doses. Contraindications include men with a history of hypersensitivity to alprostadil, men at risk of priapism, and men with bleeding disorders. Despite these favourable data, drop-out rates of 41-68% have been described for intracavernous pharmacotherapy [143, 144, 147, 148], with most drop-outs occurring within the first 2-3 months. In a comparative study, alprostadil monotherapy had the lowest discontinuation rate (27.5%) compared to overall drug combinations (37.6%), with an attrition rate after the first few months of therapy of 10% per year. Reasons for discontinuation included desire for a permanent modality of therapy (29%), lack of a suitable partner (26%), poor response (23%) (especially among early drop-out patients), fear of needles (23%), fear of complications (22%), and lack of spontaneity (21%). Careful counselling of patients during the office-training phase as well as close follow-up

is important in addressing patient withdrawal from an intracavernous injection programme [149].

3A.4.6.1.2 Combination therapy

Combination therapy enables a patient to take advantage of the different modes of action of the drugs being used, as well as alleviating side-effects by using lower doses of each drug.

- Papaverine (20-80 mg) was the first oral drug used for intracavernous injections. It is most commonly used in combination therapy due to its high incidence of side-effects as monotherapy. Currently unlicensed.
- Phentolamine has been used in combination therapy to increase efficacy. As monotherapy, it produces a poor erectile response.
- Sparse data in the literature support the use of other drugs, such as vasoactive intestinal peptide (VIP), NO donors (linsidomine), forskolin, potassium channel openers, moxislyte or calcitonin gene-related peptide, usually combined with the main drugs [150, 151]. Most combinations are not standardised and some drugs have limited availability worldwide.
- Papaverine (7.5-45 mg) plus phentolamine (0.25-1.5 mg), and papaverine (8-16 mg) plus phentolamine (0.2-0.4 mg) plus alprostadil (10-20 µg), have been widely used with improved efficacy rates, although they have never been licensed for ED [152, 153]. The triple combination regimen of papaverine, phentolamine and alprostadil has the highest efficacy rates, reaching 92%; this combination has similar side-effects as alprostadil monotherapy, but a lower incidence of penile pain due to lower doses of alprostadil. However, fibrosis is more common (5-10%) when papaverine is used (depending on total dose).
- VIP (25 µg) + phentolamine mesylate (1-2 mg) (Invicorp™, currently licensed in Scandinavia), is a combination of two active components with complementary modes of action. Clinical studies showed that the combination is an effective treatment for intracavernous injections in ≥ 80% of men with ED, including those who have failed to respond to other therapies and, unlike existing intracavernosal therapies, is associated with a very low incidence of penile pain and virtually negligible risk of priapism [154].

Despite high efficacy rates, 5-10% of patients do not respond to combination intracavernous injections. The combination of sildenafil with intracavernous injection of the triple combination regimen may salvage as many as 31% of patients who do not respond to the triple combination alone [155]. However, combination therapy is associated with an incidence of adverse effects in 33% of patients, including dizziness in 20% of patients. This strategy can be considered in carefully selected patients before proceeding to a penile implant [Level 4].

3A.4.6.1.3 Intraurethral/topical alprostadil

A specific formulation of alprostadil (125-1000 µg) in a medicated pellet (MUSE™) has been approved as a treatment for ED [156]. Erections sufficient for intercourse are achieved in 30-65.9% of patients. In clinical practice, only the higher doses (500 and 1000 µg) have been used with low consistency response rates [156-158]. The application of a constriction ring at the root of the penis (ACTIS™) may improve efficacy [157, 158]. The most common adverse events are local pain (29-41%) and dizziness with possible hypotension (1.9-14%). Penile fibrosis and priapism are very rare (< 1%). Urethral bleeding (5%) and urinary tract infections (0.2%) are adverse events related to the mode of administration. Efficacy rates are significantly lower than intracavernous pharmacotherapy [142]. Intraurethral pharmacotherapy is a second-line therapy and provides an alternative to intracavernous injections in patients who prefer a less-invasive, although less-efficacious treatment. Topical alprostadil is another way of giving alprostadil. It is actually a cream that includes a permeation enhancer in order to facilitate absorption of alprostadil (200 and 300µg) through the urethral meatus [159]. Clinical data are limited. Significant improvement compared to placebo was recorded for IIEF, SEP2 and SEP3 in a broad range of patients with mild to severe ED [160]. Side-effects include penile erythema, penile burning and pain. Systemic side-effects are very rare. Topical alprostadil is approved and it is available in some European countries.

3A.4.7 **Third-line therapy (penile prostheses)**

The surgical implantation of a penile prosthesis may be considered in patients who do not respond to pharmacotherapy or who prefer a permanent solution to their problem. The two currently available classes of penile implants include inflatable (2- and 3-piece) and malleable devices [31, 81, 161, 162]. Most patients prefer the 3-piece inflatable devices due to the more “natural” erections obtained. Likewise, 3-piece inflatable devices provide the best rigidity and the best flaccidity because they will fill every part of the corporal bodies. However, the 2-piece inflatable prosthesis can be a viable option among patients who are deemed high-risk of complications with reservoir placements. Malleable prostheses result in a firm penis, which may be manually placed in an erect or flaccid state [31, 81, 161, 162].

There are two main surgical approaches for penile prosthesis implantation: penoscrotal and infrapubic [161-164]. The penoscrotal approach provides an excellent exposure, it affords proximal crural exposure if necessary, avoids dorsal nerve injury and permits direct visualisation of pump placement. However, with this approach the reservoir is blindly placed into the retropubic space, which can be a problem in patients with a history of major pelvic surgery (mainly radical cystectomy). The infrapubic approach has the advantage of reservoir placement under direct vision, but the implantation of the pump may be more challenging, and patients are at a slightly increased risk of dorsal nerve injury. Revision surgery is associated with decreased outcomes and may be more challenging. Regardless of the indication, prosthesis implantation has one of the highest satisfaction rates (92-100% in patients and 91-95% in partners) among the treatment options for ED based on appropriate consultation [31, 81, 161, 165-171]. In patients with favourable oncologic prognosis after RP for PCa, combination surgery for treatment of ED, with the implant of a penile prosthesis, and stress urinary incontinence (male sling or artificial urinary sphincter) is effective and durable and has an established, definitive role to address this problem [31, 81, 172-174].

3A.4.7.1 Complications

The two main complications of penile prosthesis implantation are mechanical failure and infection. Several technical modifications of the most commonly used 3-piece prosthesis (AMS 700CX/CXRTM and Coloplast Alpha ITM) resulted in mechanical failure rates of < 5% after 5 years of follow-up [81, 175, 176]. Careful surgical techniques with proper antibiotic prophylaxis against Gram-positive and Gram-negative bacteria reduces infection rates to 2-3% with primary implantation in low-risk patients. The infection rate may be further reduced to 1-2% by implanting an antibiotic-impregnated prosthesis (AMS Inhibizone™) or hydrophilic-coated prosthesis (Coloplast Titan™) [81, 177-180]. Higher risk populations include patients undergoing revision surgery, those with impaired host defenses (immunosuppression, diabetes mellitus, spinal cord injury) or those with penile corporal fibrosis [9, 81, 161, 181-183]. Infection requires removal of the prosthesis and antibiotic administration. Alternatively, removal of the infected device with immediate replacement with a new prosthesis has been described using a washout protocol with successful salvages achieved in > 80% of cases [181, 183, 184]. The majority of revisions are secondary to mechanical failure and combined erosion or infection. Ninety three percent of cases are successfully revised, providing functioning penile prosthesis.

3A.4.7.2 Conclusions third-line therapy

Penile implants are an attractive solution for patients who do not respond to more conservative therapies. There is sufficient evidence to recommend this approach in patients not responding to less-invasive treatments due to its high efficacy, safety and satisfaction rates.

3A.4.8 Recommendations for the treatment of ED

	LE	GR
Lifestyle changes and risk factor modification must precede or accompany ED treatment.	1a	A
Pro-erectile treatments have to be given at the earliest opportunity after RP.	1b	A
When a curable cause of ED is found, it must be treated first.	1b	B
PDE5Is are first-line therapy.	1a	A
Inadequate/incorrect prescription and poor patient education are the main causes of a lack of response to PDE5Is.	3	B
A VED can be used in patients with a stable relationship.	4	C
Intracavernous injection is second-line therapy.	1b	B
Penile implant is third-line therapy.	4	C

ED = erectile dysfunction; RP = radical prostatectomy; VED = vacuum erection devices; PDE5I = phosphodiesterase type 5 [inhibitors].

3A.5 Follow-up

Follow-up is important in order to assess efficacy and safety of the treatment provided. It is also essential to assess patient satisfaction since a successful treatment for ED goes beyond efficacy and safety. Physicians must be aware that there is no single treatment that fits all patients or all situations as described in detail in the previous section.

3B PREMATURE EJACULATION

3B.1 Epidemiology/aetiology/pathophysiology

Although premature ejaculation (PE) is a common male sexual dysfunction, it is poorly understood. Patients are often unwilling to discuss their symptoms and many physicians do not know about effective treatments. As a result, patients may be misdiagnosed or mistreated [2].

3B.1.1 Epidemiology

The major problem in assessing the prevalence of PE is the lack of an accurate (validated) definition at the time the surveys were conducted [185]. The highest prevalence rate of 31% (men aged 18-59 years) was found by the National Health and Social Life Survey (NHSL) study in USA [186]. Prevalence rates were 30% (18-29 years), 32% (30-39 years), 28% (40-49 years) and 55% (50-59 years). It is, however, unlikely that the PE prevalence is as high as 20–30% based on the relatively low number of men who present for treatment of PE. These high prevalence rates may be a result of the dichotomous scale (yes/no) in a single question asking if ejaculation occurred too early, as the prevalence rates in European studies have been significantly lower [187]. According to the four PE subtypes proposed by Waldinger et al [188], the prevalence rates were 2.3% (lifelong PE), 3.9% (acquired PE), 8.5% (natural variable PE) and 5.1% (premature-like ejaculatory dysfunction) [189]. An approximately 5% prevalence of acquired PE and lifelong PE in general populations is consistent with epidemiological data indicating that around 5% of the population have an ejaculation latency less than 2 minutes [190].

3B.1.2 Pathophysiology and risk factors

The aetiology of PE is unknown, with little data to support suggested biological and psychological hypotheses, including anxiety, penile hypersensitivity, and 5-HT receptor dysfunction [191]. In addition, the pathophysiology of PE is largely unknown. All the physiological events leading up to the forceful expulsion of sperm at the urethral meatus are not impaired in PE patients. A significant proportion of men with ED also experience PE [192]. High levels of performance anxiety related to ED may worsen PE, with a risk of misdiagnosing PE instead of the underlying ED. According to the NHLS, the prevalence of PE is not affected by age [186, 187], unlike ED, which increases with age. PE is not affected by marital or income status [186]. However, PE is more common in black men, Hispanic men and men from Islamic backgrounds [193, 194] and may be higher in men with a lower educational level [186, 192]. Other risk factors may include a genetic predisposition [195], poor overall health status and obesity [186], prostate inflammation [196, 197], thyroid hormone disorders [37], emotional problems and stress [186, 198], and traumatic sexual experiences [186, 192]. In the only published study on risk modification/prevention strategies [199], successful eradication of causative organisms in patients with chronic prostatitis and PE produced marked improvements in IELT and ejaculatory control compared to untreated patients [200].

3B.1.3 Impact of PE on QoL

Men with PE are more likely to report low satisfaction with their sexual relationship, low satisfaction with sexual intercourse, difficulty relaxing during intercourse, and less frequent intercourse [201, 202]. However, the negative impact of PE extends beyond sexual dysfunction. PE can have a detrimental effect on self-confidence and the relationship with the partner, and may sometimes cause mental distress, anxiety, embarrassment and depression [201, 203]. Sex drive and overall interest in sex does not appear to be affected by PE [204]. However, the partner's satisfaction with the sexual relationship decreases with increasing severity of the man's condition [205]. Despite the possible serious psychological and QoL consequences of PE, few men seek treatment. In the GSSAB survey, 78% of men who self-reported a sexual dysfunction sought no professional help or advice for their sexual problems [192], with men more likely to seek treatment for ED than for PE [192]. In the PEPA survey, only 9% of men with self-reported PE consulted a doctor [187]. The main reasons for not discussing PE with their physician are patient embarrassment and a belief that there is no treatment. Physicians are often uncomfortable discussing sexuality with their patients usually because of embarrassment and a lack of training or expertise in treating PE [206, 207]. Physicians need to encourage their patients to talk about PE.

3B.2 Classification

There have previously been two official definitions of PE, neither of which have been universally accepted:

- In the Diagnostic and Statistical Manual of Mental Disorders IV-Text Revision (DSM-IV-TR), PE is defined as a '*persistent or recurrent ejaculation with minimal sexual stimulation before, on, or shortly after penetration and before the person wishes it. The clinician must take into account factors that affect duration of the excitement phase, such as age, novelty of the sexual partner or situation, and recent frequency of sexual activity*' [208]. This DSM definition has been recently updated in the DSM V edition [209].

- In the World Health Organization's International Classification of Diseases-10 (ICD-10), PE is defined as *'the inability to delay ejaculation sufficiently to enjoy lovemaking, which is manifested by either an occurrence of ejaculation before or very soon after the beginning of intercourse (if a time limit is required: before or within 15 seconds of the beginning of intercourse) or ejaculation occurs in the absence of sufficient erection to make intercourse possible. The problem is not the result of prolonged absence from sexual activity'* [210].

The Second International Consultation on Sexual and Erectile Dysfunction defined PE as:

'ejaculation with minimal stimulation and earlier than desired, before or soon after penetration, which causes bother or distress, and over which the sufferer has little or no voluntary control' [191].

The International Society for Sexual Medicine (ISSM) has adopted a completely new definition of PE which is the first evidence-based definition [211]:

PE (lifelong and acquired) is a male sexual dysfunction characterised by the following:

1. Ejaculation that always or nearly always occurs prior to or within about 1 minute of vaginal penetration (lifelong PE) or a clinically significant and bothersome reduction in latency time, often to about 3 minutes or less (acquired PE).
2. The inability to delay ejaculation on all or nearly all vaginal penetrations.
3. Negative personal consequences, such as distress, bother, frustration, and/or the avoidance of sexual intimacy.

All four definitions have taken into account the time to ejaculation, the inability to control or delay ejaculation, and negative consequences (bother/distress) from PE. However, the major point of debate is quantifying the time to ejaculation, which is usually described by intravaginal ejaculatory latency time (IELT) [209].

Recently, two more PE syndromes have been proposed [212]:

- 'Variable PE' is characterised by inconsistent and irregular early ejaculations, representing a normal variation in sexual performance.
- 'Subjective PE' is characterised by subjective perception of consistent or inconsistent rapid ejaculation during intercourse, while ejaculation latency time is in the normal range or can even last longer. It should not be regarded as a symptom or manifestation of true medical pathology.

The addition of these new types may aid patient stratification, diagnosis and treatment, but their exact role remains to be defined [213].

3B.3 Diagnostic evaluation

Diagnosis of PE is based on the patient's medical and sexual history [214, 215]. History should classify PE as lifelong or acquired and determine whether PE is situational (under specific circumstances or with a specific partner) or consistent. Special attention should be given to the duration time of ejaculation, degree of sexual stimulus, impact on sexual activity and QoL, and drug use or abuse. It is also important to distinguish PE from ED. Many patients with ED develop secondary PE caused by the anxiety associated with difficulty in attaining and maintaining an erection [216]. Furthermore, some patients are not aware that loss of erection after ejaculation is normal and may erroneously complain of ED, while the actual problem is PE [217]. There are several overlapping definitions of PE, with four shared factors (Table 7), resulting in a multidimensional diagnosis [218].

Table 7: Common factors in different definitions of ED

•	Time to ejaculation assessed by IELT
•	Perceived control
•	Distress
•	Interpersonal difficulty related to the ejaculatory dysfunction

3B.3.1 Intravaginal ejaculatory latency time

The use of IELT alone is not sufficient to define PE, as there is significant overlap between men with and without PE [219, 220]. IELT has a significant direct effect on perceived control over ejaculation, but not a significant direct effect on ejaculation-related personal distress or satisfaction with sexual intercourse [221]. In addition, perceived control over ejaculation has a significant direct effect on both ejaculation-related personal distress and satisfaction with sexual intercourse (each showing direct effects on interpersonal difficulty related to ejaculation). In everyday clinical practice, self-estimated IELT is sufficient [222]. Self-estimated and

stopwatch-measured IELT are interchangeable and correctly assign PE status with 80% sensitivity and 80% specificity [223]. Specificity can be improved further to 96% by combining IELT with a single-item patient-reported outcome (PRO) on control over ejaculation and satisfaction with sexual intercourse (scale ranging from 0 = very poor to 4 = very good) and on personal distress and interpersonal difficulty (0 = not at all to 4 = extremely). However, stopwatch-measured IELT is necessary in clinical trials. While IELT is an objective tool for PE assessment, a recent study reported that sexual satisfaction and distress correlated more strongly with the feeling of control than with the self-reported latency time [224].

3B.3.2 PE assessment questionnaires

The need to assess PE objectively has led to the development of several questionnaires based on the use of PROs [218]. Only two questionnaires can discriminate between patients who have PE and those who do not:

- Premature Ejaculation Diagnostic Tool (PEDT): five-item questionnaire based on focus groups and interviews from the USA, Germany and Spain. Assesses control, frequency, minimal stimulation, distress and interpersonal difficulty [225, 226]. A total score ≥ 11 suggests a diagnosis of PE, a score of 9 or 10 suggests a probable diagnosis of PE while a score of ≤ 8 indicates a low likelihood of PE.
- Arabic Index of Premature Ejaculation (AIPE): seven-item questionnaire developed in Saudi Arabia assesses sexual desire, hard erections for sufficient intercourse, time to ejaculation, control, satisfaction for the patient and partner, anxiety or depression [227]. A cut-off score of 30 (range of scores 7-35) discriminated best PE diagnosis. Severity of PE was classified as severe (score: 7-13), moderate (score: 14-19), mild to moderate (score: 20-25) and mild (score: 26-30).

The most widely used tool is the PEDT. However, there is a low correlation between a diagnosis provided by PEDT and a self-reported diagnosis. A recent study reported that only 40% of men with PEDT-diagnosed PE and 19% of men with probable PE self-reported the condition [228]. Questionnaires are a significant step in simplifying the methodology of PE drug studies, although further cross-cultural validation is needed [229]. Other questionnaires used to characterise PE and determine treatment effects include the PEP [220], Index of Premature Ejaculation (IPE) (61) and Male Sexual Health Questionnaire Ejaculatory Dysfunction (MSHQ-EjD) [230]. Currently, their role is optional in everyday clinical practice.

3B.3.3 Physical examination and investigations

Physical examination may be part of the initial assessment of men with PE. It may include a brief examination of the endocrine and neurological systems to identify underlying medical conditions associated with PE or other sexual dysfunctions, such as endocrinopathy, Peyronie's disease, urethritis or prostatitis. Laboratory or physiological testing should be directed by specific findings from history or physical examination and is not routinely recommended [214].

3B.3.4 Recommendations for the diagnostic evaluation of PE

Recommendations	LE	GR
Diagnosis and classification of PE is based on medical and sexual history. It should be multidimensional and assess IELT, perceived control, distress and interpersonal difficulty due to the ejaculatory dysfunction.	1a	A
Clinical use of self-estimated IELT is adequate. Stopwatch-measured IELT is necessary in clinical trials.	2a	B
Patient-reported outcomes (PROs) have the potential to identify men with PE. Further research is needed before PROs can be recommended for clinical use.	3	C
Physical examination may be necessary in initial assessment of PE to identify anatomical abnormalities that may be associated with PE or other sexual dysfunctions, particularly ED.	3	C
Routine laboratory or neurophysiological tests are not recommended. They should only be directed by specific findings from history or physical examination.	3	C

PE = premature ejaculation; IELT = intravaginal ejaculatory latency time; ED = erectile dysfunction.

3B.4 Disease management

In men for whom PE causes few, if any problems, treatment is limited to psychosexual counselling and education. Before beginning treatment, it is essential to discuss the patient's expectations thoroughly. Furthermore, it is important to treat first, if present, ED especially and possibly prostatitis.

Various behavioural techniques have been beneficial in treating PE and are indicated for patients uncomfortable

with pharmacological therapy. In lifelong PE, behavioural techniques are not recommended for first-line treatment. They are time-intensive, require the support of a partner and can be difficult to perform. In addition, long-term outcomes of behavioural techniques for PE are unknown.

Pharmacotherapy is the basis of treatment in lifelong PE. Dapoxetine is the only on-demand pharmacological treatment approved for PE in many countries except for the USA. All other medications used in PE are off-label indications. Chronic antidepressants including selective serotonin reuptake inhibitors (SSRIs) and clomipramine, a tricyclic antidepressant and on-demand topical anaesthetic agents have consistently shown efficacy in PE. Long-term outcomes for pharmacological treatments are unknown.

An evidence-based analysis of all current treatment modalities was performed. Levels of evidence and grades of recommendation are provided and a treatment algorithm is presented (Figure 4).

3B.4.1 **Psychological/behavioural strategies**

Behavioural strategies mainly include the 'stop-start' programme developed by Semans [231] and its modification, the 'squeeze' technique, proposed by Masters and Johnson:

- In the 'stop-start' programme, the partner stimulates the penis until the patient feels the urge to ejaculate. At this point, he instructs his partner to stop, waits for the sensation to pass and then stimulation is resumed.
- The 'squeeze' technique is similar but the partner applies manual pressure to the glans just before ejaculation until the patient loses his urge.

Both these procedures are typically applied in a cycle of three pauses before proceeding to orgasm.

Behavioural strategies are based on the hypothesis that PE occurs because the man fails to appreciate the sensations of heightened arousal and to recognise the feelings of ejaculatory inevitability. Re-training may attenuate stimulus-response connections by gradually exposing the patient to progressively more intense and more prolonged stimulation, while maintaining the intensity and duration of the stimulus just below the threshold for triggering the response. There are several modifications of these techniques making comparison difficult.

Masturbation before anticipation of sexual intercourse is a technique used by younger men. Following masturbation, the penis is desensitised resulting in greater ejaculatory delay after the refractory period is over. In a different approach, the man learns to recognise the signs of increased sexual arousal and how to keep his level of sexual excitement below the intensity that elicits the ejaculatory reflex. Efficacy is similar to the 'Stop-start' programme [232].

Psychological factors may be associated with PE and should be addressed in treatment. These factors, if any, mainly relate to anxiety, but could also include relationship factors. The limited studies available suggest that behavioural therapy, as well as functional sexological treatment, lead to improvement in the duration of intercourse and sexual satisfaction.

Overall, short-term success rates of 50-60% have been reported [233, 234]. However, there is no controlled research to support the efficacy of behavioural techniques, while a double-blind, randomised, crossover study showed that pharmacological treatment (clomipramine, sertraline, paroxetine and sildenafil) resulted in greater IELT prolongation than behavioural therapy [235]. Furthermore, clinical experience suggests that improvements achieved with these techniques are generally not maintained long-term [236, 237]. Behavioural therapy may be most effective when used to 'add value' to medical interventions, although this suggestion requires proof from further randomised clinical trials. Validated assessment instruments need to be used as end-points. Longer follow-up periods are necessary to confirm these findings.

3B.4.2 **Dapoxetine**

Dapoxetine hydrochloride is a short-acting SSRI, with a pharmacokinetic profile suitable for on-demand treatment for PE. It has a rapid T_{max} (1.3 hours) and a short half-life (95% clearance rate after 24 hours) [238]. Dapoxetine has been investigated in 6081 subjects to date [239]. It is approved for on-demand treatment of PE in European countries and elsewhere, but not in the USA.

Both available doses of dapoxetine (30 mg and 60 mg) have shown 2.5- and 3.0-fold increases, respectively, in IELT overall, rising to 3.4- and 4.3-fold in patients with baseline average IELT < 0.5 minutes [240, 241]. In RCTs, dapoxetine, 30 mg or 60 mg 1-2 hours before intercourse, was effective from the first dose on IELT and increased ejaculatory control, decreased distress, and increased satisfaction. Dapoxetine has shown a similar efficacy profile in men with lifelong and acquired PE [241]. Treatment-related side-effects were dose-

dependent and included nausea, diarrhoea, headache and dizziness. Side-effects were responsible for study discontinuation in 4% (30 mg) and 10% (60 mg) of subjects [222]. There was no indication of an increased risk of suicidal ideation or suicide attempts and little indication of withdrawal symptoms with abrupt dapoxetine cessation [242].

Regarding a combination of PDE5 inhibitors with dapoxetine, the addition of dapoxetine to a given regimen of PDE5 inhibitor may increase the risk of possible prodromal symptoms that may progress to syncope compared to both PDE5 inhibitors and SSRIs administered alone. Generally, when dapoxetine is co-administered with a PDE5 inhibitor, it is well tolerated, with a safety profile consistent with previous phase 3 studies of dapoxetine alone [243]. A low rate of vasovagal syncope was reported in phase 3 studies. According to the summary of product characteristics, orthostatic vital signs (blood pressure and heart rate) must be measured prior to starting dapoxetine. No cases of syncope were observed in a post-marketing observational study, which had identified patients at risk for orthostatic reaction using the patient's medical history and orthostatic testing [244].

The mechanism of action of short-acting SSRIs in PE is still speculative. Dapoxetine resembles the antidepressant SSRIs in the following ways: the drug binds specifically to the 5-HT reuptake transporter at subnanomolar levels, has only a limited affinity for 5-HT receptors and is a weak antagonist of the 1A-adrenoceptors, dopamine D1 and 5-HT_{2B} receptors. The rapid absorption of dapoxetine might lead to an abrupt increase in extracellular 5HT following administration that might be sufficient to overwhelm the compensating autoregulation processes. Does the mechanism of action of short-acting SSRIs differ from that of the conventional chronic SSRI mechanism of action? Either such agents do not cause the autoreceptor activation and compensation reported using chronic SSRIs, or these effects occur, but they simply cannot prevent the action of short-acting SSRIs [245].

3B.4.3 Off-label use of antidepressants: SSRIs and clomipramine

Ejaculation is commanded by a spinal ejaculation generator [246, 247] under excitatory or inhibitory influences from the brain and the periphery [248]. 5-hydroxytryptamine (5-HT or serotonin) is involved in ejaculatory control, with its ejaculation-retarding effects likely to be attributable to activation of 5-HT_{1B} and 5-HT_{2C} receptors, both spinally and supraspinally. By contrast, stimulation of 5-HT_{1A} receptors precipitates ejaculation [245].

Selective serotonin reuptake inhibitors (SSRIs) are used to treat mood disorders, but can delay ejaculation and are therefore widely used 'off-label' for PE. As for depression, SSRIs must be given for 1 to 2 weeks to be effective in PE [245]. Administration of chronic SSRIs causes prolonged increases in synaptic cleft serotonin, which desensitises the 5-HT_{1A} and 5-HT_{1B} receptors [249]. Clomipramine, the most serotonergic tricyclic antidepressant, was first reported in 1973 as an effective PE treatment [250]. SSRIs have revolutionised treatment of PE, but they have also changed our understanding of PE since the first publication on paroxetine in 1970 [251]. Before dapoxetine, daily treatment with SSRIs was the first choice of treatment in PE. Commonly used SSRIs include citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline, all of which have a similar pharmacological mechanism of action.

A systematic review and meta-analysis of all drug treatment studies reported that, despite methodological problems in most studies, there still remained several, well-designed, double-blind, placebo-controlled trials supporting the therapeutic effect of daily SSRIs on PE [252]. Nevertheless, despite significant increase in IELT, there are no data available concerning the PROs in PE patients treated with daily SSRIs.

Based on this meta-analysis, SSRIs were expected to increase the geometric mean IELT by 2.6-fold to 13.2-fold. Paroxetine was found to be superior to fluoxetine, clomipramine and sertraline. Sertraline was superior to fluoxetine, whereas the efficacy of clomipramine was not significantly different from fluoxetine and sertraline. Paroxetine was evaluated in doses of 20-40 mg, sertraline 25-200 mg, fluoxetine 10-60 mg and clomipramine 25-50 mg; there was no significant relationship between dose and response among the various drugs. There is limited evidence that citalopram may be less efficacious compared to other SSRIs, while fluvoxamine may not be effective [253, 254].

Ejaculation delay may start a few days after drug intake, but it is more evident after 1 to 2 weeks since receptor desensitisation requires time to occur. Although efficacy may be maintained for several years, tachyphylaxis (decreasing response to a drug following chronic administration) may occur after 6 to 12 months [250]. Common side-effects of SSRIs include fatigue, drowsiness, yawning, nausea, vomiting, dry mouth, diarrhoea and perspiration; they are usually mild and gradually improve after 2 to 3 weeks [213, 240]. Decreased libido,

anorgasmia, anejaculation and ED have also been reported.

Because of a theoretical risk of suicidal ideation or suicide attempts, caution is suggested in prescribing SSRIs to young adolescents with PE aged 18 years or less, and to men with PE and a comorbid depressive disorder, particularly when associated with suicidal ideation. Patients should be advised to avoid sudden cessation or rapid dose reduction of daily dosed SSRIs which may be associated with a SSRI withdrawal syndrome [222].

In one controlled trial, on-demand use of clomipramine (but not paroxetine), 3 to 5 hours before intercourse, was reported to be efficacious, though IELT improvement was inferior compared to daily treatment with the same drug [255]. However, on-demand treatment may be combined with an initial trial of daily treatment or concomitant low-dose daily treatment reducing adverse effects [256, 257].

Individual countries' regulatory authorities strongly advise against prescribing medication for indications if the medication in question is not licensed/approved and prescription of off-label medication may present difficulties for physicians.

3B.4.4 Topical anaesthetic agents

The use of local anaesthetics to delay ejaculation is the oldest form of pharmacological therapy for PE [258]. Several trials [259, 260] support the hypothesis that topical desensitising agents reduce the sensitivity of the glans penis so delaying ejaculatory latency, but without adversely affecting the sensation of ejaculation.

3B.4.4.1 Lidocaine-prilocaine cream

In a randomised, double-blind, placebo-controlled trial, lidocaine-prilocaine cream increased the IELT from 1 minute in the placebo group to 6.7 minutes in the treatment group [261]. In another randomised, double-blind, placebo-controlled trial, lidocaine-prilocaine cream significantly increased the stopwatch-measured IELT from 1.49 to 8.45 minutes while no difference was recorded in the placebo group (1.67 to 1.95 minutes) [262].

Lidocaine-prilocaine cream (5%) is applied for 20-30 minutes prior to intercourse. Prolonged application of topical anaesthetic (30-45 minutes) may result in loss of erection due to numbness of the penis in a significant percentage of men [261]. A condom will prevent diffusion of the topical anaesthetic agent into the vaginal wall causing numbness in the partner.

Alternatively, the condom may be removed prior to sexual intercourse and the penis washed clean of any residual active compound. Although no significant side-effects have been reported, topical anaesthetics are contraindicated in patients or partners with an allergy to any part of the product.

An experimental aerosol formulation of lidocaine, 7.5 mg, plus prilocaine, 2.5 mg (Topical Eutectic Mixture for Premature Ejaculation [TEMPE]), was applied 5 minutes before sexual intercourse in 539 males. There was an increase in the geometric mean IELT from a baseline of 0.58 minutes to 3.17 minutes during 3 months of double-blind treatment; a 3.3-fold delay in ejaculation compared with placebo ($p < 0.001$) [263].

3B.4.5 Tramadol

Tramadol is a centrally acting analgesic agent that combines opioid receptor activation and re-uptake inhibition of serotonin and noradrenaline. Tramadol is readily absorbed after oral administration and has an elimination half-life of 5-7 hours. For analgesic purposes, tramadol can be administered between 3 and 4 times daily in tablets of 50-100 mg. Side-effects were reported at doses used for analgesic purposes (up to 400 mg daily) and include constipation, sedation and dry mouth. Tramadol is a mild-opioid receptor agonist, but it also displays antagonistic properties on transporters of noradrenaline and 5-HT [264]. This mechanism of action distinguishes tramadol from other opioids, including morphine. However, in May 2009, the US Food and Drug Administration released a warning letter about tramadol's potential to cause addiction and difficulty in breathing [265].

A large, randomised, double-blind, placebo-controlled, multicentre 12-week study was carried out to evaluate the efficacy and safety of two doses of tramadol (62 and 89 mg) by orally disintegrating tablet (ODT) in the treatment of PE [266]. Previously, a bioequivalence study had previously been performed that demonstrated equivalence between tramadol ODT and tramadol HCl. In patients with a history of lifelong PE and an IELT < 2 minutes, increases in the median IELT of 0.6 minutes (1.6-fold), 1.2 minutes (2.4-fold) and 1.5 minutes (2.5-fold) were reported for placebo, 62 mg of tramadol ODT, and 89 mg of tramadol ODT, respectively. It should be noted that there was no dose-response effect with tramadol. The tolerability during the 12-week study period was acceptable.

Overall, tramadol has shown a moderate beneficial effect with a similar efficacy as dapoxetine. From what is known about the neuropharmacology of ejaculation and the mechanism of action of tramadol, the delaying effect on ejaculation could be explained by combined CNS μ -opioid receptor stimulation and increased brain 5-HT availability. However, efficacy and tolerability of tramadol would have to be confirmed in more patients and longer-term.

3B.4.6 **Other drugs**

3B.4.6.1 *Phosphodiesterase type 5 inhibitors*

There is only one well-designed, randomised, double-blind, placebo-controlled study comparing sildenafil to placebo [267]. Although IELT was not significantly improved, sildenafil increased confidence, the perception of ejaculatory control and overall sexual satisfaction, reduced anxiety and decreased the refractory time to achieve a second erection after ejaculation.

Several open-label studies showed that sildenafil combined with an SSRI is superior to SSRI monotherapy:

- Sildenafil combined with paroxetine improved IELT significantly and satisfaction vs. paroxetine alone [268].
- Sildenafil combined with sertraline improved IELT and satisfaction significantly vs. sertraline alone [269].
- Sildenafil combined with paroxetine and psychological and behavioural counselling significantly improved IELT and satisfaction in patients in whom other treatments failed [270].
- Finally, sildenafil combined with behavioural therapy significantly improved IELT and satisfaction vs. behavioural therapy alone [271].

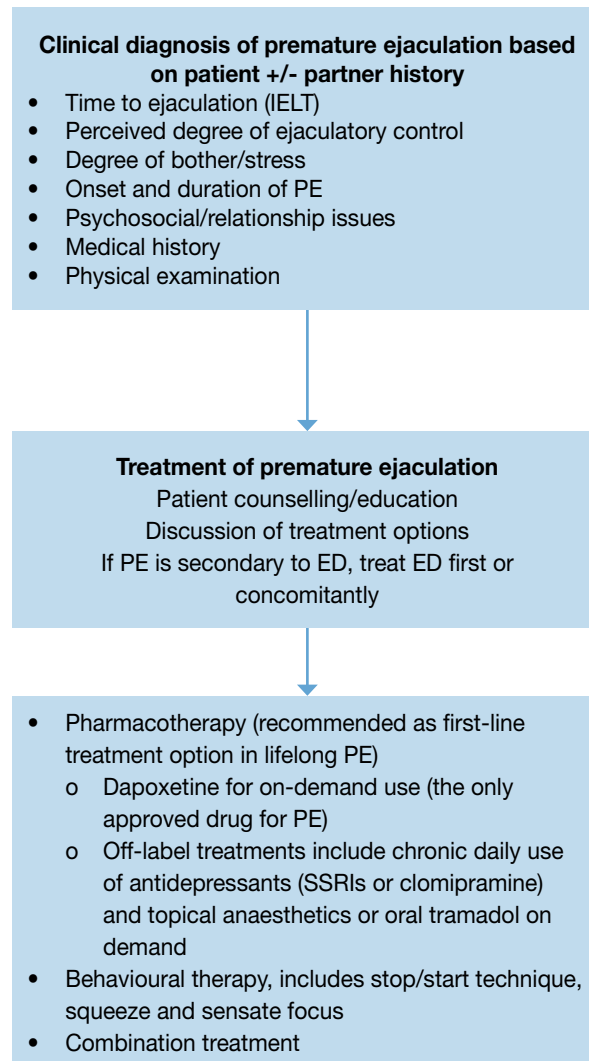

There are very limited data on the efficacy of other PDE5Is (tadalafil and vardenafil) [272, 273]. The role of PDE5Is in PE patients without ED is not established, with only minimal double-blind placebo controlled data available.

3B 4.7 **Recommendations for the treatment of PE**

Recommendations	LE	GR
Erectile dysfunction, other sexual dysfunction or genitourinary infection (e.g. prostatitis) should be treated first.	2a	B
Pharmacotherapy should be given as first-line treatment of lifelong premature ejaculation.	1a	A
Pharmacotherapy includes either dapoxetine on demand (a short-acting SSRI that is the only approved pharmacological treatment for premature ejaculation) or other off-label antidepressants, i.e. daily SSRIs and clomipramine, that are not amenable to on-demand dosing. With all antidepressant treatment for premature ejaculation, recurrence is likely after treatment cessation.	1a	A
Off-label topical anaesthetic agents can be offered as a viable alternative to oral treatment with SSRIs.	1b	A
Behavioural and sexological therapies have a role in the management of acquired premature ejaculation. They are most likely to be best used in combination with pharmacological treatment.	3	C
Psychological/behavioural therapies.	3	C
On-demand treatment of premature ejaculation		
PDE5 inhibitor.	3	C
Dapoxetine on demand.	1a	A
Tramadol on demand.	2a	B
Chronic treatment of premature ejaculation		
Off-label chronic treatment i.e. daily with selective serotonin receptor inhibitors (SSRIs) and clomipramine antidepressants.	1a	A
On-demand topical therapy for premature ejaculation		
Lidocaine-prilocaine cream.	1b	A

SSRI = selective serotonin reuptake inhibitor.

Figure 4: Management of PE*

* Adapted from Lue et al. 2004 [274].

ED = erectile dysfunction; PE = premature ejaculation; IELT = intravaginal ejaculatory latency time;

SSRI = selective serotonin receptor inhibitor.

4. FOLLOW-UP

Follow-up is important in order to assess efficacy and safety of the provided treatment as well as the satisfaction of the patient and his partner as discussed in detail in the previous section.

1. INTRODUCTION

1.1 Aim

Priapism is a pathological condition representing a true disorder of penile erection that persists for more than 4 hours and is beyond, or is unrelated to, sexual interest or stimulation [1] (LE: 4). Overall, erections lasting up to 4 hours are by consensus defined as 'prolonged' (LE: 4).

Priapism may occur at all ages. The incidence rate of priapism in the general population is low (0.5-0.9 cases per 100,000 person-years) [2, 3]. In patients with sickle cell disease, the prevalence of priapism is up to 3.6% in patients < 18 years of age [4] increasing up to 42% in patients ≥ 18 years of age [5-8].

The aim of these guidelines is to present the current evidence for the diagnosis and treatment of patients suffering from priapism.

1.2 Publication history

The EAU Guidelines on Priapism were first published in 2014 by the EAU Male Sexual Dysfunction Guidelines Panel.

This 2015 version has been updated and re-formatted according to the EAU template for non-oncology Guidelines, so that all Guidelines follow a similar format.

Alongside a scientific publication [9], a quick reference document (Pocket Guidelines) is available, both in print and in a number of versions for mobile devices, presenting the main findings of the Priapism Guidelines. These are abridged versions which may require consultation together with the full text versions. All available material can be viewed and downloaded for personal use at the EAU website. The EAU website also includes a selection of EAU Guidelines articles as well as translations produced by national urological associations: <http://www.uroweb.org/guidelines/online-guidelines/>.

This document was peer-reviewed prior to publication.

1.3 Panel composition

The EAU Male Sexual Dysfunction Guidelines Panel consists of urologists. Members of this Panel have been selected based on their expertise to represent the professionals treating patients suffering from priapism.

2. METHODS

References used in this text are graded according to their Level of Evidence (LE) and Guidelines are given a Grade of Recommendation (GR). In this 2015 EAU Guidelines compilation, all standard information on LE and GR has been taken out of the individual Guidelines topics for the sake of brevity. The methodology section (see the introduction chapter of the complete book) outlines the LE and GR criteria which are used throughout the Guidelines, according to a classification system modified from the Oxford Centre for Evidence-based Medicine Levels of Evidence.

The EAU Guidelines on Priapism are based on a systematic literature search performed by the Panel members. The MedLine database was searched using the major Medical Subject Headings term 'priapism' with search cut-off date of October 2014. This search yielded 1,688 articles (192 review articles, 485 original articles and 911 case reports). The Panel also identified critical problems and knowledge gaps, enabling priorities to be established for future clinical research.

3. THE GUIDELINE

3A ISCHAEMIC (LOW-FLOW OR VENO-OCCLUSIVE) PRIAPISM

3A.1 Epidemiology/aetiology/pathophysiology

Ischaemic priapism is the most common form of priapism, accounting for more than 95% of all priapism episodes [10, 11]. It is usually painful, with a rigid erection characterised clinically by absent or reduced intracavernous arterial inflow. In ischaemic priapism, there are time-dependent modifications in the corporal metabolic environment, progressively leading to hypoxia, hypercapnia, and acidosis.

Ischaemic priapism beyond 4 hours is considered a compartment syndrome, characterised by supraphysiological pressure within the closed space of the corpora cavernosa, which severely compromises cavernous circulation. Emergency medical intervention is required to minimise potential irreversible consequences, such as corporal fibrosis and permanent erectile dysfunction (ED) [12, 13]. The duration of priapism represents the most significant predictor of the development of ED. In this context, interventions beyond 48-72 hours since onset may help to relieve erection and pain, but have little benefit in preventing ED.

Histologically, by 12 hours, corporal specimens show interstitial oedema, progressing to destruction of sinusoidal endothelium, exposure of the basement membrane and thrombocyte adherence at 24 hours. At 48 hours, thrombi can be found in the sinusoidal spaces and smooth muscle necrosis with fibroblast-like cell transformation is evident [13]. In terms of pathophysiology (Table 1), no specific cause can be identified in the majority of cases [11, 14]. However, ischaemic priapism can be associated with sickle cell disease, haematological dyscrasias, neoplastic syndromes, and with the use of several different medications. Ischaemic priapism may occur (0.4-35%) after intracavernous injections of erectogenic agents [11, 12, 15-17]. The risk is highest with papaverine-based combinations, while the risk of priapism is < 1% following prostaglandin E1 injection [17].

Since their introduction on the market, a few cases of priapism have been described in men who have taken phosphodiesterase type 5 inhibitors (PDE5Is) [11]. Most of these men however, had other risk factors for priapism, and it is unclear whether PDE5Is alone can cause ischaemic priapism [11]. Since most men who experienced priapism following PDE5I use had additional risk factors for ischaemic priapism, PDE5I use is usually not regarded a risk factor in itself.

Sickle cell disease is the most common cause in childhood, accounting for 63% of the cases. It is the primary aetiology in 23% of adult cases [18], with a lifetime probability of developing ischaemic priapism of 29-42% in men with sickle cell disease [11, 18-20] (LE: 4). Mechanisms of sickle cell disease associated priapism may involve dysfunctional nitric oxide synthase and ROCK signaling, and increased oxidative stress associated with NADPH oxidase mediated signaling [21].

Priapism resulting from metastatic or regional infiltration is rare and usually reflects an infiltrative process [22]. As such, the recommendations for pharmacological treatment are unlikely to work and certainly all of these men should have a magnetic resonance imaging (MRI) scan and be offered supportive care for their primary cancer.

Priapism in children is extremely rare and is most commonly related to malignancy, haematological or otherwise. The investigative focus should be on identifying any underlying causes.

Partial priapism, or idiopathic partial thrombosis of the penis, is a very rare condition. It is a subtype of priapism limited to the crura. Its aetiology is unknown, but bicycle riding, trauma, drug usage, sexual intercourse, haematological diseases and α -blockers have been associated with partial priapism [23].

Table 1: Potential causative factors for ischaemic priapism

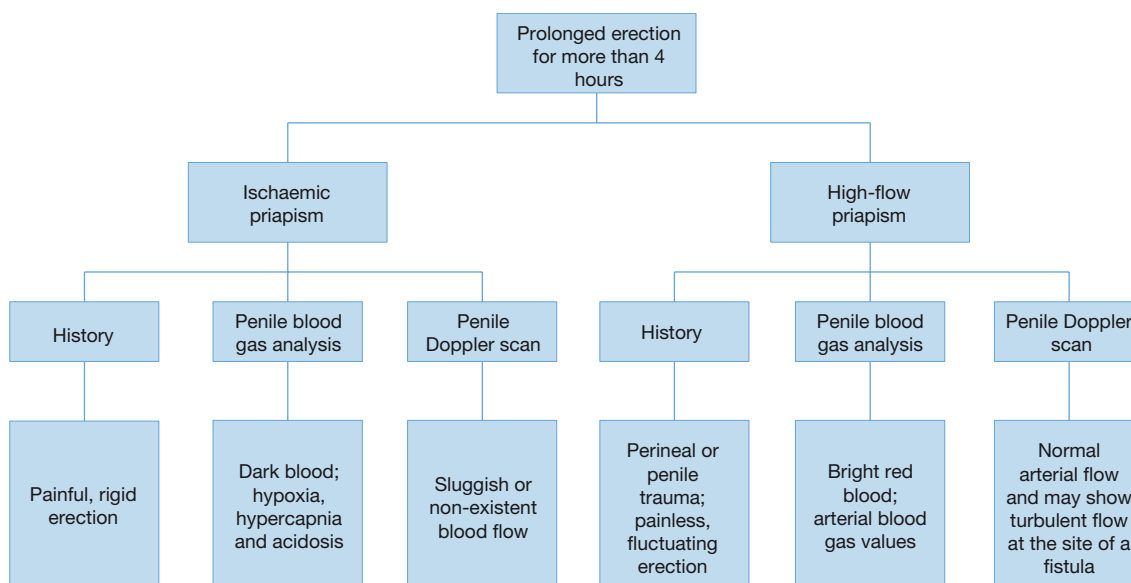

• Idiopathic
• Haematological dyscrasias (sickle cell disease, thalassemia, leukaemia; multiple myeloma, Hb Olmsted variant, fat emboli during hyperalimentation, haemodialysis, glucose-6-phosphate dehydrogenase deficiency, Factor V Leiden mutation)
• Infections (toxin-mediated) (i.e. scorpion sting, spider bite, rabies, malaria)
• Metabolic disorders (i.e. amyloidosis, Fabry's disease, gout)
• Neurogenic disorders (i.e. syphilis, spinal cord injury, cauda equina syndrome, autonomic neuropathy, lumbar disc herniation, spinal stenosis, cerebrovascular accident, brain tumour, spinal anaesthesia)
• Neoplasms (metastatic or regional infiltration) (i.e. prostate, urethra, testis, bladder, rectal, lung, kidney)
• Medications
o Vasoactive erectile agents (i.e. papaverine, phentolamine, prostaglandin E1/alprostadil, combination of intracavernous therapies)
o Alpha-adrenergic receptor antagonists (i.e. prazosin, terazosin, doxazosin, tamsulosin)
o Antianxiety agents (hydroxyzine)
o Anticoagulants (heparin, warfarin)
o Antidepressants and antipsychotics (i.e. trazodone, bupropion, fluoxetine, sertraline, lithium, clozapine, risperidone, olanzapine, chlorpromazine, thiorizadine, phenothiazines)
o Antihypertensives (i.e. hydralazine, guanethidine, propranolol)
o Hormones (i.e. gonadotropin-releasing hormone, testosterone)
o Recreational drugs (i.e. alcohol, marijuana, cocaine [intranasal and topical], crack, cocaine)

3A.1.1 Conclusions on the epidemiology, aetiology and pathophysiology of ischaemic priapism

Conclusions	LE
Ischaemic priapism is most common, accounting for more than 95% of all cases.	1b
Ischaemic priapism is identified as idiopathic in the vast majority of patients, while sickle cell anaemia is the most common cause in childhood.	1b
Ischaemic priapism occurs relatively often (up to 35%) after intracavernous injections of papaverine-based combinations, while it is rare (< 1%) after prostaglandin E1 monotherapy.	2a
Priapism is rare in men who have taken PDE5Is with only sporadic cases reported.	1a

3A.1.2 Classification

Ischaemic priapism is a persistent erection marked by rigidity of the corpora cavernosa and by little or no cavernous arterial inflow [11]. The patient typically complains of penile pain and examination reveals a rigid erection. Resolution of ischaemic priapism is characterised by return to a flaccid non-painful state. However, in many cases, persistent penile oedema, ecchymosis and partial erections can occur and may mimic unresolved priapism. The partial erections may reflect reactive hyperaemia and are sometimes misdiagnosed as persistent priapism. When left untreated, resolution may take days and ED invariably results.

Figure 1: Differential diagnosis of priapism**3A.1.3.1 History**

A comprehensive history taking is the mainstay in priapism diagnosis [11, 24]. The medical history must include a history of sickle cell disease or any other haematological abnormality [8, 25] and a history of pelvic, genital or perineal trauma. The sexual history must include complete details of the duration of erection, the presence and degree of pain, prior medical drug use, any previous history of priapism and erectile function prior to the last priapism episode (Table 2). The history can help to determine the underlying type of priapism (Table 3). Ischaemic priapism is associated with progressive penile pain and the erection is rigid.

Table 2: Key points in taking the history of priapism (adapted from Broderick et al [11])

Duration of erection
Presence and degree of pain
Previous episodes of priapism and method of treatment
Current erectile function, especially the use of any erectogenic therapies prescription or nutritional supplements
Medications and recreational drugs
Sickle cell disease, haemoglobinopathies, hypercoagulable states
Trauma to the pelvis, perineum, or penis

3A.1.3.2 Physical examination

In ischaemic priapism, the corpora are fully rigid and tender, but the glans penis is soft. The patient complains of pain. Pelvic examination may reveal cases of malignancy.

3A.1.3.3 Laboratory testing

Laboratory testing should include a complete blood count, white blood count with blood cell differential, platelet count and coagulation profile to assess anaemia and detect haematological abnormalities [11, 24].

Blood aspiration from the corpora cavernosa shows dark ischaemic blood (Table 3) (LE: 2b). Blood gas analysis is essential to differentiate between ischaemic and arterial priapism (Table 4).

Further laboratory testing should be directed by history, clinical and laboratory findings. These may include specific tests for the diagnosis of sickle cell anaemia or other haemoglobinopathies (e.g. haemoglobin electrophoresis) or urine and plasma toxicological studies when there is suspected use of recreational psychoactive drugs.

3A.1.3.4 Penile imaging

Colour Doppler ultrasound (US) of the penis and perineum is recommended and can differentiate ischaemic from arterial priapism as an alternative or adjunct to blood gas analysis [26-28] (LE: 2b). Scanning of the penis should be performed before aspiration in ischaemic priapism.

Examination of the penile shaft and perineum is recommended. In ischaemic priapism there will be an absence of blood flow in the cavernous arteries. The return of the cavernous artery waveform will result in successful detumescence [11, 28, 29]. After aspiration, a reactive hyperaemia may develop with a high arterial flow that may mislead the diagnosis as arterial priapism.

The role of MRI in the diagnostic evaluation of priapism is controversial. It may be helpful in cases of ischaemic priapism to assess the viability of the corpora cavernosa and the presence of penile fibrosis. In a prospective study in 38 patients with ischaemic priapism, the sensitivity of MRI in predicting non-viable smooth muscle was 100%, as confirmed by corporal biopsy [30]. In this study, all patients with viable smooth muscle on MRI maintained erectile function on clinical follow-up (LE: 3).

Table 3: Key findings in priapism (adapted from Broderick et al [11])

	Ischaemic priapism	Arterial priapism
Corpora cavernosa fully rigid	Usually	Seldom
Penile pain	Usually	Seldom
Abnormal penile blood gas	Usually	Seldom
Haematological abnormalities	Usually	Seldom
Recent intracorporeal injection	Sometimes	Sometimes
Perineal trauma	Seldom	Usually

Table 4: Typical blood gas values (adapted from Broderick et al [11])

Source	pO ₂ (mmHg)	pCO ₂ (mmHg)	pH
Normal arterial blood (room air) [similar values are found in arterial priapism]	> 90	< 40	7.40
Normal mixed venous blood (room air)	40	50	7.35
Ischaemic priapism (first corporal aspirate)	< 30	> 60	< 7.25

3A.1.3.5 Recommendations for the diagnosis of ischaemic priapism

Recommendations	GR
A comprehensive history is key for diagnosis and can help to determine the underlying type of priapism.	B
Physical examination of the genitalia, the perineum and the abdomen must be included in the diagnostic evaluation and may help to determine the underlying type of priapism.	B
Laboratory testing should include complete blood count, white blood count with blood cell differential, platelet count and coagulation profile. Further laboratory testing should be directed by the history and clinical and laboratory findings. Priapism in children requires a complete evaluation of all possible causes.	B
Blood gas analysis of blood aspirated from the penis is recommended for the differentiation between ischaemic and arterial priapism.	B
Colour duplex ultrasound of the penis and perineum is recommended for the differentiation between ischaemic and arterial priapism as an alternative or adjunct to blood gas analysis. It can also be helpful in localisation of the site and extend of fistula in arterial priapism as well as in the determination of successful resolution of ischaemic priapism.	B
Magnetic resonance imaging of the penis can predict smooth muscle viability and erectile function restoration.	B
Selected pudendal arteriogram should be reserved for the management of arterial priapism when embolisation is undertaken.	B

3A.1.4 Disease management

Acute ischaemic priapism is an emergency condition. Rapid intervention is compulsory (LE: 4), and should follow a stepwise approach. The aim of any treatment is to restore penile flaccidity, without pain, in order to prevent damage to the corpora cavernosa.

Figure 2: Treatment of ischaemic priapism

The treatment is sequential and the physician should move on to the next stage if the treatment fails.

(*) The dose of phenylephrine should be reduced in children. It can result in significant hypertension and should be used with caution in men with cardiovascular disease and monitoring of pulse, blood pressure and electrocardiogram (ECG) is advisable in all patients during administration and for 60 minutes afterwards. Its use is contraindicated in men with a history of cerebro-vascular disease and significant hypertension.

3A.1.4.1 First-line treatments

First-line treatments in ischaemic priapism of > 4 hours duration are strongly recommended before any surgical treatment (LE: 4). Conversely, first-line treatments initiated beyond 72 hours while relieving the priapism have little documented benefit in terms of potency preservation (LE: 4).

Historically, several first-line treatments have been described including exercise, ejaculation, ice packs, cold baths, and cold water enemas [11]. However, there is lack of evidence of benefit for such measures.

Partial priapism usually resolves spontaneously with analgesic treatment while surgical intervention is rarely needed [31].

3A.1.4.1.1 Penile anaesthesia/systemic analgesia

It is possible to perform blood aspiration and intracavernosal injection of a sympathomimetic agent without any anaesthesia. However, anaesthesia may be necessary when there is severe penile pain. While it is recognised that the anaesthesia may not alleviate the ischaemic pain, cutaneous anaesthesia will facilitate subsequent therapies. The treatment options for penile anaesthesia/systemic analgesia include:

- dorsal nerve block;
- circumferential penile block;
- subcutaneous local penile shaft block;
- oral conscious sedation (for paediatric patients).

3A.1.4.1.2 Aspiration ± irrigation with 0.90% w/v saline solution

The first intervention for an episode of priapism lasting > 4 hours consists of corporal aspiration (LE: 4) to

drain stagnant blood from the corporal bodies, making it possible to relieve the compartment syndrome-like condition of the penis. Blood aspiration may be performed with intracorporeal access either through the glans or via percutaneous needle access on the lateral aspect of the proximal penile shaft, using a 16G or 18G angiocatheter or butterfly needle. The needle must penetrate the skin, the subcutaneous tissue and the tunica albuginea to drain the corpus cavernosum (LE: 4).

Some clinicians use two angiocatheters or butterfly needles at the same time to accelerate drainage, as well as aspirating and irrigating simultaneously with a saline solution [19] (LE: 4). Aspiration should be continued until fresh red, oxygenated, blood is aspirated (LE: 4).

This approach has up to a 30% chance of terminating the priapism. There are insufficient data to determine whether aspiration followed by saline intracorporeal irrigation is more effective than aspiration alone (LE: 4).

3A.1.4.1.3 Aspiration ± irrigation with 0.90% w/v saline solution in combination with intracavernosal injection of pharmacological agents

This combination is currently considered the standard of care in the treatment of ischaemic priapism [1, 11, 32] (LE: 4). Pharmacological agents include sympathomimetic drugs or alpha-adrenergic agonists. Options for intracavernosal sympathomimetic agents include phenylephrine, etilephrine, ephedrine, epinephrine, norepinephrine and metaraminol with a resolution rate of up to 80%. [11, 32-40] (LE: 2b). The use of intracavernosal adrenalin injection alone has also been sporadically reported [41].

3A.1.4.1.3.1 Phenylephrine

Phenylephrine is currently the drug of choice due to its high selectivity for the alpha-1-adrenergic receptor, without concomitant beta-mediated inotropic and chronotropic cardiac effects [33, 37, 38] (LE: 4).

Phenylephrine is diluted in normal saline to a concentration of 100-500 µg/mL. Usually 200 µg are given every 3-5 minutes directly into the corpus cavernosum. Maximum dosage is 1 mg within 1 hour (LE: 4). A lower concentration or volume is applicable for children and patients with severe cardiovascular disease (LE: 4).

Phenylephrine use has potential cardiovascular side-effects [11, 32-34, 37, 38] and it is recommended that blood pressure and pulse are monitored every 15 minutes for an hour after the injection. This is particularly important in older men with existing cardiovascular diseases. After injection, the puncture site should be compressed and the corpora cavernosa massaged to facilitate drug distribution.

The potential treatment-related side-effects of intracavernous phenylephrine (and other sympathomimetic agents) include headache, dizziness, hypertension, reflex bradycardia, tachycardia and palpitations, irregular cardiac rhythms and sporadic subarachnoid haemorrhage [34]. Monitoring of blood pressure and pulse with ECG should be performed during intracavernous administration of sympathomimetic agents.

Overall, the administration of intracavernosal sympathomimetic agents is contraindicated in patients suffering from malignant or poorly controlled hypertension and in those who are concurrently taking monoamine oxidase inhibitors (LE: 4).

3A.1.4.1.3.2 Etilephrine

Etilefrine is the second most widely used sympathomimetic agent, administered by intracavernosal injection at a concentration of 2.5 mg in 1-2 ml normal saline [34] (LE: 3).

3A.1.4.1.3.3 Methylene blue

Methylene blue is a guanylate cyclase inhibitor, which may be a potential inhibitor of endothelial-mediated cavernous relaxation. It has therefore been suggested for treating short-term pharmacologically induced priapism [42, 43] (LE: 3). Methylene blue, 50-100 mg [42], should be injected intracavernously and left for 5 minutes. It is then aspirated and the penis compressed for an additional 5 minutes [43]. Treatment-related side-effects include a transient burning sensation and blue discolouration of the penis.

3A.1.4.1.3.4 Adrenaline

Intracavernosal adrenaline (dosage of 2 mL of 1/100,000 adrenaline solution up to five times over a 20-minute period [41]), has been used in patients with ischaemic priapism due to an intracavernosal injection of vasoactive agents. Success rate of over 50% after a single injection, with an overall success rate of 95% with repeated injections is achieved (LE: 3).

3A.1.4.1.3.5 Oral terbutaline

Oral terbutaline is a beta-2-agonist with minor beta-1 effects and some alpha-agonist activity. A dose of 5 mg has been suggested to treat prolonged erections lasting more than 2.5 hours, after intracavernosal injection of vasoactive agents, although the mechanism of action is not yet fully understood [44-46] (LE: 1b). Its main use is in the prevention of recurrent episodes of prolonged erection. Terbutaline should be given cautiously in patients with coronary artery disease, increased intravascular fluid volume, oedema and hypokalaemia [46].

Table 5: Medical treatment of ischaemic priapism

Drug	Dosage/Instructions for use
Phenylephrine	<ul style="list-style-type: none">- Intracavernous injection of 200 µg every 3-5 minutes.- Maximum dosage is 1 mg within 1 hour.- The lower doses are recommended in children and patients with severe cardiovascular disease.
Etilephrine	<ul style="list-style-type: none">- Intracavernosal injection at a concentration of 2.5 mg in 1-2 ml normal saline.
Methylene blue	<ul style="list-style-type: none">- Intracavernous injection of 50-100 mg, left for 5 minutes. It is then aspirated and the penis compressed for an additional 5 minutes.
Adrenaline	<ul style="list-style-type: none">- Intracavernous injection of 2 mL of 1/100,000 adrenaline solution up to five times over a 20-minute period.
Terbutaline	<ul style="list-style-type: none">- Oral administration of 5 mg for prolonged erections lasting more than 2.5 hours, after intracavernosal injection of vasoactive agents.

3A.1.4.1.4 Management of sickle cell disease related priapism

Rapid intervention is essential (LE: 4) and the general approach is similar to that described in other cases of ischaemic priapism [47-49] (LE: 4).

However, as with other haematological disorders, other therapeutic practices may also need to be implemented [47, 49, 50]. Specific measures for sickle cell disease related priapism include intravenous hydration and parental narcotic analgesia while preparing the patient for aspiration and irrigation. In addition, supplemental oxygen administration and alkalinisation with bicarbonate can be helpful [20, 48].

Exchange blood transfusion has also been proposed, with the aim of increasing the tissue delivery of oxygen. The transfused blood should be HbS negative, Rh and Kell antigen matched [51]. However, the evidence is inconclusive as to whether exchange transfusion itself helps to resolve the priapism in these men. It should also be noted that several reports suggest that this treatment may result in serious neurological sequelae [52]. Because of these considerations, the routine use of this therapy is not recommended (LE: 4).

3A.1.4.2 Second-line treatments

Second-line intervention typically refers to surgical intervention in the form of penile shunt surgery and should only be considered when conservative management options fail (LE: 4). There is no evidence detailing the amount of time allowed for first-line treatment before moving on to surgery. Consensus recommendations suggest a period of at least 1 hour of first-line therapy prior to moving to surgery (LE: 4). A number of clinical indicators suggest failure of first-line treatment including continuing corporal rigidity, cavernosal acidosis and anoxia, absence of cavernosal artery inflow by penile colour duplex US, and elevated intracorporal pressures by pressure monitoring (LE: 4).

3A.1.4.2.1 Penile shunt surgery

Penile shunt surgery aims to produce an exit for ischaemic blood from the corpora cavernosa thereby allowing the restoration of normal circulation within these structures. Accordingly, any shunt creates an opening in the tunica albuginea, which may communicate with either the glans, the corpus spongiosum or a vein for blood drainage [11, 32, 53].
